SECOND EDITION

EDITED BY

Michael L. Bentz, MD, FACS, FAAP

Layton F. Rikkers, MD, Chair of Surgical Leadership;
Professor of Surgery, Pediatrics and Neurology;
Chairman, Division of Plastic and Reconstructive Surgery;
Vice Chairman of Clinical Affairs, Department of Surgery,
University of Wisconsin School of Medicine and Public Health,
Madison, Wisconsin

Bruce S. Bauer, MD, FACS, FAAP

Director of Pediatric Plastic Surgery,
NorthShore University HealthSystem, Highland Park Hospital;
Clinical Professor of Surgery, Pritzker School of Medicine,
University of Chicago,
Chicago, Illinois

Ronald M. Zuker, MD, FRCSC, FACS, FAAP, FRCSEd(Hon)

Professor of Surgery, Department of Surgery
The University of Toronto; Consultant Plastic Surgeon,
The Division of Plastic and Reconstructive Surgery,
The Hospital for Sick Children,
Toronto, Ontario, Canada

Director, Editorial Services: Mary Jo Casey
International Production Director: Andreas Schabert
International Marketing Director: Fiona Henderson
International Sales Director: Louisa Turrell
Director of Sales, North America: Mike Roseman
Senior Vice President and Chief Operating Officer: Sarah Vanderbilt
President: Brian D. Scanlan

**Library of Congress Cataloging-in-Publication Data
is available from the publisher upon request.**

Important note: Medicine is an ever-changing science undergoing continual development. Research and clinical experience are continually expanding our knowledge, in particular our knowledge of proper treatment and drug therapy. Insofar as this book mentions any dosage or application, readers may rest assured that the authors, editors, and publishers have made every effort to ensure that such references are in accordance with **the state of knowledge at the time of production of the book.**

Nevertheless, this does not involve, imply, or express any guarantee or responsibility on the part of the publishers in respect to any dosage instructions and forms of applications stated in the book. **Every user is requested to examine carefully** the manufacturers' leaflets accompanying each drug and to check, if necessary in consultation with a physician or specialist, whether the dosage schedules mentioned therein or the contraindications stated by the manufacturers differ from the statements made in the present book. Such examination is particularly important with drugs that are either rarely used or have been newly released on the market. Every dosage schedule or every form of application used is entirely at the user's own risk and responsibility. The authors and publishers request every user to report to the publishers any discrepancies or inaccuracies noticed. If errors in this work are found after publication, errata will be posted at www.thieme.com on the product description page.

Some of the product names, patents, and registered designs referred to in this book are in fact registered trademarks or proprietary names even though specific reference to this fact is not always made in the text. Therefore, the appearance of a name without designation as proprietary is not to be construed as a representation by the publisher that it is in the public domain.

This book, including all parts thereof, is legally protected by copyright. Any use, exploitation, or commercialization outside the narrow limits set by copyright legislation without the publisher's consent is illegal and liable to prosecution. This applies in particular to photostat reproduction, copying, mimeographing or duplication of any kind, translating, preparation of microfilms, and electronic data processing and storage.

*For Kim, Gretchen, Alex, and Eric, who continue to make it hard to be at work,
because it is so fun being at home.*

M.L.B.

*To my wife, Sally, for unwavering support throughout my career, and acceptance
of her role as muse for my creative efforts, both surgical and artistic; to my family,
Erik and Mandy; and to my grandsons, Carson and Graham, who continue to provide
an example of how to keep life in balance.*

B.S.B.

*To my parents, Philip and Esther, who allowed and encouraged me to pursue
my dreams; to my wife, Gail, who keeps me focused and on track; to my children,
Jeremy, Andrew, and Philip, for their energy and inspiration; and to my adorable
grandchildren, Jack, Ryan, and Luke, for making it all worthwhile.*

Contributors

Lee W.T. Alkureishi, MBChB

Pediatric Plastic Surgery and Craniofacial Fellow, NorthShore University HealthSystem, and Shriners Hospital for Children, Chicago, Illinois

Benjamin Alman, MD

Chair, Department of Orthopaedic Surgery, Duke University Medical Center, Durham, North Carolina

Seth A. Alpert, MD, FACS, FAAP

Clinical Associate Professor of Urology, Section of Pediatric Urology, Department of Pediatric Surgery, Nationwide Children's Hospital and The Ohio State University Wexner Medical Center, Columbus, Ohio

Martin Beldin Anixter, MD

Assistant Professor of Anesthesia, Department of Anesthesiology, The Children's Hospital of Pittsburgh of the University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Jugal S. Arneja, MD, MBA, FACS, FAAP, FRCSC

Clinical Professor, Division of Plastic Surgery, Department of Surgery, University of British Columbia; Attending Plastic Surgeon and Associate Chief, Department of Surgery, British Columbia's Children's Hospital, Vancouver, British Columbia, Canada

Kodi Azari, MD, FACS

Professor and Chief, Section of Reconstructive Transplantation, Department of Orthopedic Surgery and Plastic Surgery, David Geffen School of Medicine at the University of California, Los Angeles, Los Angeles, California

Stephen B. Baker, MD, DDS, FACS, FAAP

Professor and Program Director, Department of Plastic Surgery, Georgetown University Hospital; Medical Director, Craniofacial Program, Inova Children's Hospital, Washington, D.C.

Bruce S. Bauer, MD, FACS, FAAP

Director of Pediatric Plastic Surgery, NorthShore University HealthSystem, Highland Park Hospital; Clinical Professor of Surgery, Pritzker School of Medicine, University of Chicago, Chicago, Illinois

Michael L. Bentz, MD, FACS, FAAP

Layton F. Rikkers, MD, Chair of Surgical Leadership; Professor of Surgery, Pediatrics and Neurology; Chairman, Division of Plastic and Reconstructive Surgery; Vice Chairman of Clinical Affairs, Department of Surgery, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Brendan Bernhart, DDS, PC

Prosthodontic and Maxillofacial Prosthetic Surgeon, Fairfax, Virginia

Gregory H. Borschel, MD, FACS, FAAP

Associate Professor, Department of Surgery, The University of Toronto; Consultant Plastic Surgeon, The Division of Plastic and Reconstructive Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada

Ashley Buba, MS, CCC-SLP

Speech-Language Pathologist, Craniofacial and Reconstructive Plastic Surgery Center, Dell Children's Medical Center, University of Texas at Austin, Austin, Texas

Reuben A. Bueno, Jr., MD

Chief of Pediatric Plastic Surgery, Monroe Carell, Jr. Children's Hospital at Vanderbilt University; Associate Professor and Residency Program Director, Department of Plastic Surgery, Vanderbilt University Medical Center, Nashville, Tennessee

Fernando D. Burstein, MD, FACS, FAAP

Director, Center for Craniofacial Disorders, Children's Healthcare of Atlanta; Clinical Professor, Division of Plastic Surgery, Emory University, Atlanta, Georgia

Daniel R. Butz, MD

Resident, Section of Plastic and Reconstructive Surgery, University of Chicago, Chicago, Illinois

Earl Y. Cheng, MD, FACS, FAAP

Professor of Urology, Division of Urology, Ann and Robert H. Lurie Children's Hospital of Chicago and Northwestern University Feinberg School of Medicine, Chicago, Illinois

Brian M. Christie, MD

Resident, Department of Surgery, Division of Plastic Surgery, University of Wisconsin Hospitals and Clinics, Madison, Wisconsin

Franklyn P. Cladis, MD, FAAP

Associate Professor of Anesthesiology, Department of Anesthesiology, The Children's Hospital of Pittsburgh of the University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania

Howard M. Clarke, MD, PhD, FRCSC, FACS, FAAP

Professor of Surgery, Department of Surgery, The University of Toronto; Active Staff Surgeon, The Division of Plastic and Reconstructive Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada

Christopher J. Coombs, MBBS(Hons), FRACS(Plast)

Clinical Professor, Department of Plastic and Maxillofacial Surgery, The Royal Children's Hospital, Melbourne, Victoria, Australia

Julia Corcoran, MD, MHPE

Associate Professor of Surgery, Division of Plastic Surgery, Northwestern University Feinberg School of Medicine; Attending Surgeon, Ann and Robert H. Lurie Children's Hospital of Chicago, Chicago, Illinois

Kristen M. Davidge, MD, MSc, FRCSC

Assistant Professor, Department of Surgery, The University of Toronto; Consultant Plastic Surgeon, The Division of Plastic and Reconstructive Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada

Frederic White-Brown Deleyiannis, MD, MPhil, MPH, FACS

Professor and Chief, Department of Pediatric Plastic Surgery, Director of Craniofacial Microsurgery and Trauma, Interim Director of Cleft and Craniofacial Program, Departments of Surgery and Otolaryngology, Children's Hospital Colorado and The University of Colorado Denver School of Medicine, Aurora, Colorado

Sandhya Deo, BHB, MBChB, FRACS

Clinical Fellow, Division of Plastic and Reconstructive Surgery, The University of Toronto, Toronto, Ontario, Canada

Sara R. Dickie, MD

Clinical Educator, Department of Surgery, Section of Plastic and Reconstructive Surgery, University of Chicago Hospital, Chicago, Illinois; Surgeon, Pediatric Plastic Surgery, Department of Surgery, Division of Plastic and Reconstructive Surgery, NorthShore University HealthSystem, Northbrook, Illinois

Amir H. Dorafshar, MBChB, FACS, FAAP

Clinical Co-Director, Face Transplant Program; Associate Professor, Department of Plastic and Reconstructive Surgery, Associate Professor of Neurosurgery, The Johns Hopkins University School of Medicine, Baltimore, Maryland

Gregory A. Dumanian, MD, FACS

Chief, Division of Plastic Surgery, Northwestern University Feinberg School of Medicine, Chicago, Illinois

E. Patricia Egerszegi, MD, CM, CSPQ, FRCSC, MSc, FACS

Associate Professor, Department of Surgery,
University of Montreal, Montreal, Quebec,
Canada

Adel Y. Fattah, PhD, FRCS(Plast)

Consultant Plastic Surgeon and Director,
Facial Nerve Programme; Regional
Paediatric Burns and Plastic Surgery Service,
Alder Hey Children's NHS Foundation
Trust, Liverpool, United Kingdom

Jeffrey A. Fearon, MD, FACS, FAAP

Director, The Craniofacial Center, Medical
City Children's Hospital, Dallas, Texas

Joel Fish, MD

Medical Director, Burn Program, The
Division of Plastic and Reconstructive
Surgery, The Hospital for Sick Children;
Associate Professor, Department of Surgery,
The University of Toronto, Toronto,
Ontario, Canada

David M. Fisher, MB, BCh, FRCSC, FACS

Medical Director, The Cleft Lip and Palate
Program; Consultant Plastic Surgeon, The
Division of Plastic and Reconstructive
Surgery, The Hospital for Sick Children;
Associate Professor, Department of Surgery,
The University of Toronto, Toronto,
Ontario, Canada

Christopher R. Forrest, MD, MSc, FRCSC, FACS

Chief, Division of Plastic and Reconstructive
Surgery, Medical Director, SickKids Centre
for Craniofacial Care and Research, The
Hospital for Sick Children; Chair and
Professor, The Division of Plastic and
Reconstructive Surgery, Department of
Surgery, The University of Toronto, Toronto,
Ontario, Canada

Ravi K. Garg, MD

Resident in Plastic and Reconstructive
Surgery, Division of Plastic and
Reconstructive Surgery, University of
Wisconsin Hospitals and Clinics, Madison,
Wisconsin

Michael S. Gart, MD

Resident in Plastic and Reconstructive
Surgery, Division of Plastic Surgery,
Department of Surgery, Northwestern
Memorial Hospital, Chicago, Illinois

Mirko S. Gilardino, MD, MSc, FRCSC, FACS

Director, H.B. Williams Craniofacial and
Cleft Surgery Unit, Division of Plastic and
Reconstructive Surgery, Montreal Children's
Hospital; Associate Professor of Surgery,
McGill University Health Center, Montreal,
Quebec, Canada

John A. Girotto, MD, MMA, FACS, FAAP

Chief, Craniofacial Surgery, Division of
Pediatric Plastic Surgery, Helen DeVos
Children's Hospital; Associate Professor,
Department of Surgery, Michigan State
College of Human Medicine, Grand Rapids,
Michigan

Jesse A. Goldstein, MD

Assistant Professor, Department of Plastic
and Reconstructive Surgery, The Children's
Hospital of Pittsburgh of the University
of Pittsburgh Medical Center, Pittsburgh,
Pennsylvania

Arun K. Gosain, MD

Professor, Division of Plastic and
Reconstructive Surgery, Department of
Surgery, Northwestern University Feinberg
School of Medicine; Division Head, Division
of Pediatric Plastic Surgery, Ann and Robert
H. Lurie Children's Hospital of Chicago,
Chicago, Illinois

Lawrence J. Gottlieb, MD, FACS

Professor of Surgery, Director of Burn
and Complex Wound Center, Department
of Surgery, Section of Plastic and
Reconstructive Surgery, University of
Chicago, Chicago, Illinois

Arin K. Greene, MD, MMSc

Associate Professor of Surgery, Department
of Plastic and Oral Surgery, Boston
Children's Hospital, Harvard Medical
School, Boston, Massachusetts

Devan Griner, MD

Craniofacial Plastic Surgeon, University of Tennessee School of Medicine Chattanooga, Chattanooga, Tennessee

Thomas M. Grisius, DDS, MS

Visiting Assistant Professor, Department of Orthodontics, Virginia Commonwealth University School of Dentistry, Richmond, Virginia

Regan Guilfoyle, MD, FRCSC

Assistant Professor, Department of Plastic and Reconstructive Surgery, University of Alberta, Edmonton, Alberta, Canada

Madeleine J. Gust, MD

Chief Resident, Plastic Surgery, Division of Plastic Surgery, Department of Surgery, Northwestern University Feinberg School of Medicine, Chicago, Illinois

Raymond J. Harshbarger III, MD, FACS, FAAP

Craniofacial and Pediatric Plastic Surgery Fellowship Director and Adjunct Clinical Professor, Craniofacial and Reconstructive Plastic Surgery Center, Dell Children's Medical Center, University of Texas at Austin, Austin, Texas

Robert J. Havlik, MD

Chairman and George Korkos Professor, Department of Plastic Surgery, Medical College of Wisconsin, Milwaukee, Wisconsin

Siba Haykal, MD, PhD

Senior Resident, The Division of Plastic and Reconstructive Surgery, Department of Surgery, The University of Toronto, Toronto, Ontario, Canada

Patrick C. Hettinger, MD

Assistant Professor, Department of Plastic Surgery, Medical College of Wisconsin, Milwaukee, Wisconsin

Emily S. Ho, BScOT, MEd

Lecturer, Department of Occupational Science and Occupational Therapy, The University of Toronto; Occupational Therapist, The Division of Plastic and Reconstructive Surgery, The Hospital for Sick Children, Toronto, Ontario, Canada

William Y. Hoffman, MD, FAAP

Professor and Chief, Division of Plastic and Reconstructive Surgery; Vice Chair, Department of Surgery, University of California, San Francisco, San Francisco, California

Ronald R. Hollins, DMD, MD

Professor and Chief, Division of Plastic and Reconstructive Surgery, Department of Surgery, University of Nebraska Medical Center, Omaha, Nebraska

Sevan Hopyan, MD, PhD, FRCSC

Division of Orthopaedics and Program in Developmental and Stem Cell Biology, The Hospital for Sick Children; Associate Professor, The Departments of Surgery and Molecular Genetics, The University of Toronto, Toronto, Ontario, Canada

Jacqueline S. Israel, MD

Resident in Plastic and Reconstructive Surgery, Division of Plastic and Reconstructive Surgery, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin

Preface

We are very pleased to present this second edition of *Principles and Practice of Pediatric Plastic Surgery*. As anyone who has edited a textbook will confirm, it is a labor of love and somewhat analogous to a maternity experience. We are particularly excited to present this updated and expanded edition for your daily use in the clinical practice of pediatric plastic surgery. The first edition was successful and well received, based on feedback we have received from practicing pediatric plastic surgeons around the globe. To improve many facets of these two volumes, we worked with our talented author teams and staff at Taylor & Francis/CRC Press, specifically expanding its content for your practical utilization. We have added seven new chapters that reflect the evolving contemporary head-to-toe practice of pediatric plastic surgery, encompassing surgical techniques and nonsurgical approaches to the children in your care. As our subspecialty has evolved, so has this textbook, reflecting truly state-of-the-art contributions from experts in the field. Because 8 years have passed since the first edition was published, we believe you will notice substantial changes that will help you care for infants, children, and adolescents.

In addition to content expansion and updating, this edition offers several additional features to help you and your patients. The book is now available as an e-book with full text and illustrations, featuring expanded operative video content to help you visualize intricate techniques. We have added new illustrations and expanded photographic examples, as well as colorizing key art from the previous edition. We have deliberately kept the book as a two-volume set to make it easier to transport and use as a reference, whether at your home, hospital, or while providing global health service.

With an expanding wealth of cutting-edge information in these pages, we have tried to review the topical problems and solutions for the more common anomalies, and we also present current innovations, offering solutions for defects for which previous solutions may have been accepted but were less than optimal. Perhaps of equal or greater significance is our effort to include the additional years of follow-up (up to 8 years) for cases that have been included in updated contributor chapters, placing emphasis on how important long-term follow-up is to our specialty. Our contributors represent an international cross-section of pediatric plastic surgeons and educators who have committed their best efforts to you on your patients' behalf.

We hope that this book will provide a source of stimulation to those new to our beloved field, while also serving as a source of continued motivation for those more experienced in our specialty. For laypersons reviewing this text, we hope you will feel supported through the challenging times of parenting a child with one of the problems that are treated by pediatric plastic surgeons, and know that the future is bright for your child and the children of others as they pursue their life dreams supported by their pediatric plastic surgeon.

Michael L. Bentz
Bruce S. Bauer
Ronald M. Zuker

Acknowledgments

Although excellence in patient care drives our daily clinical effort, teaching and mentorship of junior colleagues, fellows, residents, and students are our most important educational responsibilities, and the ones that ultimately drive the future of patient care. I have been blessed to be surrounded by superb plastic surgery residents at the University of Wisconsin, Madison and the University of Pittsburgh; they have made the days (and many nights) truly worthwhile. That these junior colleagues are so far better than me in so many ways is a source of great pleasure.

For the joy and satisfaction of many wonderful and challenging professional opportunities I will always be grateful to Wallace P. Ritchie, Jr., MD, PhD (Chairman Emeritus, Temple University, Department of Surgery); the late Stuart J. Hulnick, MD (Chief of Plastic Surgery, St. Christopher's Hospital for Children, Philadelphia), Layton "Bing" Rikkers, MD (Chairman Emeritus, University of Wisconsin, Department of Surgery), K. Craig Kent, MD (Chairman, University of Wisconsin, Department of Surgery), and particularly J. William Futrell, MD (Chief of Plastic Surgery Emeritus, University of Pittsburgh). I also thank my many superb faculty partners from the University of Wisconsin and the University of Pittsburgh.

My late parents, Dr. Joe and Peggy Bentz, were phenomenally supportive during my extended educational journey. Of the few things I have accomplished as an academic plastic surgeon, none would have been possible without the love and encouragement of my wife, Kim, daughter, Gretchen, and sons, Alex and Eric. The dedication to them from my first book reads ". . . it's hard to be at work, because it is so fun being home." Nearly 20 years later, that still could not be any truer.

I want to again thank my extremely talented colleagues, friends, and co-editors, Bruce Bauer and Ron Zuker, who are truly scholars, gentlemen, and experts singularly committed to their patients, residents, and the field of plastic surgery. They are amazing role models of academic and personal excellence, and our field is better because of their multiple contributions, as am I personally.

Finally, we are indebted to the first-class staff at CRC Press, including Sue Hodgson, Megan Fennell, Kathleen Sartori, Suzanne Wakefield, Glenn Floyd, Rebecca Sweeney, Carolyn Reich, Brett Stone, Brenda Bunch, Linda Maulin, Chris Lane, Debra Clark, and Cherry Allen.

Michael L. Bentz

It is always difficult to decide who, in our personal and professional lives, has had a major influence on bringing us to this point, where some are specifically acknowledged, yet others, who may have been equally influential, are not specifically mentioned. So at the very outset, I apologize to anyone who I may have forgotten, and express my thanks for their help in whatever little accomplishments I have made.

Having grown up as the son and grandson of doctors, the choice of pursuing medicine as a career was no surprise. Both my parents, especially my mother, nurtured my artistic side and created an environment in which my sister, Laurie, and I had the tools to experiment and opportunities to reach for perfection in multiple manual crafts. Gradually, the idea of melding the science of medicine with my need to be manually creative led me to surgery.

Growing up with a father who was a child psychiatrist, I was also well aware of the potential psychological difficulties that children can face, how their feelings of self-worth are influenced by their parents and peers, and how varied forms of therapy, applied at appropriate points in their development, can profoundly affect their lives.

In the early months of medical school at Northwestern University I was introduced to the world of plastic surgery in a dazzling lecture by B. Herold Griffith, the Chief of Plastic Surgery. Approaching him afterward as an eager student, his warmth, enthusiasm, and constant desire to teach led to my decision to train in plastic surgery. He subsequently opened many doors for me: when I was still a medical student, he allowed me to become a regular visitor in the operating room at Children's Memorial Hospital, "assisting" Dr. Clarence Monroe. Later, as a resident, he connected me with my future Chief, mentor, and then partner, Dr. Desmond A. Kernahan. By the end of my training, I was committed to a career in pediatric plastic surgery.

Dr. Kernahan was a role model, with his meticulous attention to detail, innovation in surgical approach, and joy of surgery. Although he was generous in teaching me all of his tricks, he prompted me to seek my own surgical niche. This led not only to a concentrated interest in surgery of the ear, but also to a lasting relationship with our Pediatric Dermatology Service. My early work with Dr. Nancy Esterly, then Chief, launched me into the world of giant nevi, and her successors, Dr. Amy Paller and Dr. Tony Mancini, have continued to provide a never-ending supply of dermatologic challenges.

Throughout the inherent ups and downs of all academic careers, the joys of teaching residents and fellows has, I hope, provided as much inspiration for them as it has for me. I thank them all.

With my move to NorthShore University HealthSystem since the publication of our first edition, I have been blessed with an amazing group of young partners, Drs. Sara Dickie, Michael Howard, Mark Sisco, and Jeremy Warner, each of whom has shown me how enriching a mentorship relationship can be when both old skills and new talents combine to offer ever-advancing reconstructive pathways. My continued close friendship and collaborative work with my former partner, Dr. Pravin Patel, sharing our "soft tissue" and "hard tissue" expertise, continues to be a highlight of my career. All these efforts would not be possible without my exceptional nurses, Susan Hoadley and Mim Tournell, who were brave enough to make the move with me, and without whom I would not be able to accomplish half of what I do.

Without all their ongoing support I would not have had the opportunity to co-edit this book with Mike Bentz and Ron Zuker, two individuals whose many skills and accomplishments far exceed

their egos. I am honored to have this opportunity to work with both of them and am confident that our friendship will last throughout our lives.

Whatever I may have accomplished in my first three and a half decades as a pediatric plastic surgeon would not have been possible without the unwavering support of my family: Sally, who has been my confidant, muse, and love of my life for almost 40 years; our son Erik, who is now trained in the allied field of pediatric otolaryngology; his wife, Mandy, a radiologist; and our two grandsons, Carson and Graham. They are a constant reminder of the gift of having a child unburdened by many of the problems discussed in this text, and I love them more than I can say.

Finally, I must thank the many patients who have placed their trust in me and provided me with the impetus to strive for ever-better solutions to their varied problems. Organizations such as Nevus Outreach have furthered our understanding of specific defects and opened windows for comprehending the impact of that defect, not only on our patients, but also on their entire family. This brings me full circle to where I began and underscores why each of us has devoted our professional careers to this incredibly rewarding specialty of pediatric plastic surgery.

Bruce S. Bauer

As academic surgeons, our lives are so complex and intertwined with so many people and events that selecting milestones, career influences, and mentors can be extremely difficult. First, I would like to acknowledge my first Chief, Dr. W.K. Lindsay, who had the wisdom and foresight to recognize the value and potential of microsurgery in children. He gave me the opportunity and support to use this microsurgical approach to tackle complex clinical problems. I would also like to acknowledge my colleague in pediatric plastic surgery, Dr. H.G. Thomson, whose sensitive and caring manner with children and remarkable technical expertise served as my model in clinical practice.

The progress we made in microsurgery in children would not have been possible without the help of my microsurgical partner, Dr. R.T. Manktelow. His constant questioning of the status quo, searching for new solutions, and attention to detail stimulated me to the pursuit of excellence. Through the aid of a McLaughlan Traveling Fellowship from the University of Toronto, I was able to train in microsurgery in Japan under the leadership of Dr. Seichi Ohmori and Dr. Kiyonori Harii. I learned to operate using a microscope in the lab from the skilled and very patient microsurgeon, Dr. Shuhei Torii, with whom I remain close friends. Finally I learned to think outside the box and explore new concepts while training with my teacher, colleague, and friend, Dr. G. Ian Taylor. These are the mentors who supported me and allowed me to accomplish whatever small achievements I have made.

My plastic surgery colleagues, and especially those working with me at The Hospital for Sick Children, have been extremely supportive of both my clinical and academic pursuits. I would not have been able to do what I did without their help. In particular, the collaboration with my current microsurgical colleague and friend, Dr. Greg Borschel, has allowed for even greater refinements and advancements in the areas that we cherish.

In addition to my teachers and colleagues, I would also like to acknowledge the students, residents, and clinical fellows whose open minds and delving questions have stimulated me to pursue new concepts in search of better solutions.

My career has been punctuated by successes and challenges. However, no matter what, I could always depend on the support of my family as we crossed many bridges together. Although my heavy career commitment forced me to miss many of my children's milestones, we still had time to enjoy the best that life has to offer together. To my three sons and daughter-in-law, Jeremy, Melissa, Andrew, and Phil: I thank you for your patience and understanding. To my wife, Gail, of 42 years, who promised never to be upset when I was late: You have guided me, supported me, and assisted me at every turn. You are my true life partner. I thank you and will love you forever.

General Considerations in Pediatric Plastic Surgery

1

The Evolution of Pediatric Plastic Surgery

Bruce S. Bauer • Michael L. Bentz • Ronald M. Zuker

he field of pediatric plastic surgery offers endless opportunities for transforming the lives of children. As reconstructive surgeons, we can develop solutions to complex congenital conditions that previously represented insoluble problems. Although the challenges are great, the potential for positively improving the quality of life for these children is enormous. Few areas of medicine are as rewarding as pediatric plastic surgery. Our history is rich and our evolution fascinating.

HISTORICAL OVERVIEW

Historical Chinese documents from the Chin Dynasty (fourth century) clearly describe cleft lip surgery and the postoperative care required for success. In the sixteenth century, Ambroise Paré of France brought the repairs to life with his clear illustrations. Even Tagliacozzi, of rhinoplasty fame, entered the debate by emphasizing the need for muscle repair with cleft lip surgery. The masters of the past built the foundation of our current subspecialty.

Congenital nevocellular nevi are referred to in the Old Testament when Jacob selected his spotted herd.¹ After Jacob's wife Rachel gave birth to Joseph, he asked her father, Laban, to let him go. For payment for all his work over the past 20 years, he asked Laban for the spotted sheep and goats. To increase his compensation, Jacob created a striped environment from peeled branches, where the nonspotted animals would drink and mate. They bore spotted offspring that then would belong to Jacob. This substantiated the view at the time that visual stimuli can affect intrauterine development. The spots on the animals were thought to be a result of the herd's environment.

In the Middle Ages, nevi and birthmarks were blamed on the behavior of pregnant women, who were thought to be "consorting with the devil." Currently, the exact cause is not known,

be it environmental, genetic, or simply a random mutation. Although superstitions still provide explanations for congenital deformities in some parts of the world, rapid advances in the allied sciences, particularly genetics, move us toward more concrete explanations of many defects. Hopefully, these advances will lead to reduced occurrences of some deformities and provide the information necessary to modify our surgical techniques or sequences of procedures to improve the long-term outcome of our reconstructions. We are part of an ever-evolving specialty.

Pediatric plastic surgery had its origins as a specialty in 1982 with the founding of the American Association of Pediatric Plastic Surgeons. The goal of this society was to provide pediatric plastic surgeons with educational opportunities and continuity and camaraderie within the plastic surgery community. The move to raise awareness of this “new subspecialty” within the field of plastic surgery was reinforced by the subsequent formation of a Plastic Surgery Section of the American Academy of Pediatrics in 1987, which emphasized that plastic surgeons who devoted a substantial part of their practices to children and qualified to be a Fellow in the American Academy of Pediatrics (FAAP) were separate and distinct from their general pediatric surgery colleagues. As this subspecialization developed elsewhere in the world, the subspecialty of pediatric plastic surgery was born.

Pediatric plastic surgeons have become an integral part of the health care of children. As in other areas of surgery, when plastic surgeons began to focus on children and became more subspecialized, the widening recognition of their services and abilities among their colleagues and among grateful parents stimulated referrals, thereby expanding the scope of treatment. As more pediatric plastic surgeons played a role in other pediatric subspecialty clinics (such as those for dermatologic or vascular lesions), they encountered an increasing variety of difficult problems and had to find new ways to manage them. As more patients with similar problems were treated, the scope of the field widened, and a new niche was established within the field, making pediatric plastic surgeons indispensable team members at all children’s hospitals and at hospitals treating large pediatric populations.

Early pediatric plastic surgery focused on treating cleft lip and palate, microtia, and congenital hand anomalies. It quickly embraced craniofacial surgery, which led to an impressive expansion in types of treatments and surgical procedures available. Contemporary pediatric plastic surgeons have witnessed a rapid extension of treatment to regions other than the cranium, including the trunk and the extremities. At these sites, our discipline has made significant contributions, independently and with other pediatric surgery specialists and subspecialists, to the care of children with problems not commonly associated with traditional pediatric plastic surgery.

Initially, plastic surgery procedures performed in children were the same as those used in adults. Over the past 30 years, however, pediatric plastic surgery has developed its own unique procedures, and the specialty has blossomed into a vibrant area of practice. New techniques have arisen, and new problems have been solved. Advances in surgical theory, technique, and technology now offer children with deformities (and their parents) the promise of a wonderfully ordinary childhood and an opportunity to enter the adult world without the obstacles that previously marked them as outsiders.

More than just plastic surgery on little people, pediatric plastic surgery takes a typical three-dimensional reconstruction and adds a fourth dimension—time. Surgical decisions require consideration of both the effect of the surgery on growing structures and how the results will be changed by subsequent growth of the head and neck or body region. Long-term follow-up has now allowed techniques to be further refined to minimize the impact of surgery.

Although the training of plastic surgeons and general surgeons has been comingled historically, more recently the curriculum has diverged for many plastic surgeons through residency training models, the scope of practice, and independent division versus departmental adminis-

trative status. To a list of long-established craniofacial fellowships, a slowly increasing number of pediatric plastic surgery fellowships is being added to train young surgeons in the full spectrum of pediatric plastic surgery. These neophytes are not only completing their plastic surgery education but also setting the stage for a career in which pediatric plastic surgery plays a major role.

ADVANCES IN PEDIATRIC PLASTIC SURGERY

Great progress in pediatric plastic surgery has been made through the years. The advances discussed here have been essential for restoring form and function for thousands of young patients around the world.

Advances in Cleft Lip and Palate

A greater understanding of cleft anatomy and the effects of surgery on the growth process has led to significant progress in the treatment of cleft lip and palate, which in turn has led to improved outcomes and a reduced need for lip revision surgery. Presurgical orthopedics has assisted surgeons in the primary lip repair, also leading to improved outcomes. Advances in nasoalveolar molding and primary nasal repair have reduced severe nasal deformities. Cleft lip repair continues to evolve. Mohler² and Fisher³ have developed new techniques, striving toward even better results. Palatoplasty is now carried out earlier with better speech outcomes. New palatal procedures have evolved and are now well established, such as Furlow's double-opposing Z-plasty repair,⁴ which is one of the more significant palatoplasty techniques to be described in the past 75 years.

Progress has also been made in bone grafting of nasoalveolar clefts, the application of distraction osteogenesis for early treatment of select cases of severe maxillary hypoplasia, and early treatment of mandibular hypoplasia in patients with Pierre Robin sequence and in patients with syndromes affecting overall development of the facial skeleton with compromise to the airway.

Advances in Craniofacial Surgery

Craniofacial surgery is one of the areas in which some of the most impressive advances have been made in plastic surgery. Today, major improvements in operative technique allow surgeons to operate on infants with decreased blood loss, fewer complications, and increased safety. Other improvements in this area include a better understanding of the long-term effects of the various syndromic and nonsyndromic craniosynostoses on surgical outcome, the use of absorbable plate fixation, and an ever-increasing number of bone substitute materials.

In addition, pediatric craniofacial surgery has seen an increase in the use of distraction osteogenesis to treat hemifacial microsomia, mandibular hypoplasia, severe maxillary hypoplasia with airway and orbital compromise in Apert syndrome, and other severe craniosynostosis syndromes. There have been improvements in the treatment of hypertelorism and in our understanding of how growth affects the surgery. This has changed the timing of surgery to perhaps minimize the amount of relapse and limit the number of surgical interventions. Better imaging techniques and computer-based modeling and planning have had an enormous impact on the accuracy of craniofacial reconstructions and continue to evolve and facilitate improved outcomes.

Another major step forward has been an ever-expanding knowledge of the genetic basis of craniofacial syndromes, which alone may lead to a gene-based reclassification of syndromes and possible later application of gene therapy. On the technical side, the increased use of absorbable plate fixation and absorbable distraction devices has helped to limit the number of surgical procedures for these children.

Advances in Skin and Soft Tissue Reconstruction

Advances in tissue expansion for treating congenital giant nevi and large soft tissue and skin deficits of congenital and acquired origin represent another important milestone. Tissue expansion has served as an adjunct in select microvascular and craniofacial reconstructions. There are future prospects for the use of skin substitutes for resurfacing burns and congenital nevi.

New approaches to the timing of reconstruction have been instrumental in improving outcomes. Early reconstruction for complex problems such as congenital nevi and a comparison of matched cases with various reconstructive techniques lead to better-designed procedures that withstand the test of time and growth, thereby limiting the number of later reconstructive procedures required. Although early and sometimes complex surgery places a greater burden on the parents and family, an affected child may be young enough to be spared at least some of the physical pain and much of the psychological trauma of later surgery.

Advances in the Classification and Treatment of Vascular Lesions and Anomalies

A greater understanding of the biology of vascular lesions and improved classification methods have led to early medical treatment of hemangiomas, followed where needed by appropriately timed surgery. Interventional radiology for treating vascular malformations and free tissue transfer in the reconstruction of complex arteriovenous malformations is possible now, along with laser treatment of capillary vascular malformations and select hemangiomas. In addition, nonsurgical treatments are available for vascular anomalies, including sclerotherapy and embolization, either alone or as an adjunct to surgery. Therapies affecting the growth of vascular lesions at the cellular level are anticipated.

Advances in the Treatment of Trunk Anomalies

The use of “commonplace techniques” has revolutionized reconstruction of the thoracic and abdominal wall for children with the difficult omphaloceles, gastroschisis, pentalogy of Cantrell, and ectopia cordis anomalies. Patients requiring open correction of pectus excavatum are still well served by Ravitch-based techniques, relying on the routine plastic surgery principles of flap mobilization, resection of anomalous anatomy, and fixation, leading to mutually important functional and aesthetic reconstructions. Intraabdominally, microsurgical anastomosis of the hepatic artery has been shown to increase vascular patency in split-liver transplants, improving survival. Standard microvascular techniques have been successfully applied to treat patients with renal artery stenosis. The cross-pollination of these techniques would not have occurred in the absence of our daily responsibilities as the surgical cavalry for our colleagues and patients.

The Back

The back has proved to be a significant source of patient care problems and solutions. Day-of-birth flap closure of meningomyeloceles, later flap coverage of exposed back hardware, intrathoracic muscle flap transposition for bronchopleural cutaneous fistulas, and empyema dead space fill have extended survival rates for patients with historically difficult wounds.

The Breast

As improved breast procedures have been developed for treating adult patients, similar progress has occurred for pediatric and adolescent patients. Young women no longer need to live with significant breast asymmetry and hypoplasia, which directly affect socialization and healthy par-

ticipation in physical activities, such as gym class, team sports, and recreational athletic participation. More and more infants survive extended stays in the neonatal intensive care unit. The unanticipated breast size and shape consequences of early cardiac and thoracic interventions can be corrected or temporized before additional unfavorable effects occur.

Advances in Microsurgery

Replantation of amputated parts in children preserves function that far exceeds what is expected in adults. Virtually any amputated part of a child that can be replanted should be replanted. Free tissue transfer offers solutions to enhance form and function for congenital anomalies of the head and neck. These include bony and contour restoration for hemifacial microsomia and reanimation techniques with functioning muscle transplants for facial paralysis. For congenital deficiencies of the hand, procedures such as toe-to-hand transfers are performed for patients with symbrachydactyly. For children with cancer, pediatric plastic surgeons and pediatric microsurgeons are integral parts of the team approach. With improved chemotherapy, the surgical excision of sarcomas can lead to high cure rates. However, the defects of surgery, whether bony or soft tissue, require reconstruction for optimal function and quality of life. Pediatric microsurgeons can facilitate the extirpative cancer surgery by providing an acceptable functional and aesthetic reconstruction. This applies not only to soft tissue reconstruction but also to bony reconstructions and the newer joint reconstructions. Secure coverage, including the bringing in of well-vascularized tissue for allograft coverage or prosthetic joint support, vascularized bone for extensive bony defects, and even vascularized growth plate transfers, provides opportunities for surgical success in pediatric sarcoma management. Pediatric microsurgeons work with smaller but generally healthy, normal vessels and healthy children, who recover rapidly.

Advances in Other Areas

Pediatric plastic surgery has made strides in several additional areas, some involving new techniques and others relying on procedures adapted from other facets of reconstructive surgery, such as the following:

- *Ear reconstruction:* Reconstruction of the external ear for microtia and acquired ear deformities has improved, with better aesthetic outcomes, a reduced number of surgeries, and a reduced risk of complications.
- *Extremity surgery:* The treatment of congenital hand deformities; the treatment of obstetric brachial plexus injury; microvascular surgery for complex, posttraumatic composite reconstruction; and the use of distraction for congenital hypoplasia of the digits have advanced greatly in recent decades.
- *Separation of conjoined twins:* As integral members of the separation team, pediatric plastic surgeons can provide appropriate reconstruction and cover to facilitate successful separation surgery for conjoined twins.

Although significant progress has been made, much work remains to be done. Our understanding of vascular anomalies has grown substantially, but our treatment options have not expanded proportionally. We have treated these lesions in an improved anatomic and physiologic fashion, relying on a multidisciplinary effort; however, cell-specific intervention is essential.

Abdominal wall transplantation, although useful at present, should lead to a tissue-engineered solution, followed by a stem cell-mediated solution, eliminating the long-term consequences of immunosuppression in children. Significant progress has been made. However, much more work is necessary. Specifically, our treatment options for vascular anomalies fall short, despite

improvements. Perhaps a cell-specific intervention is possible. Similarly, as the era of vascularized composite allotransplantation in children nears, a tissue-engineered, stem cell-mediated solution becomes possible. Finally, a clearer understanding of fetal wound healing, tocolytic therapy, and the successful evolution of intrauterine preterm surgery will allow us to harness the vast potential of scarless healing. The challenges are endless!

Global Health in Pediatric Plastic Surgery

Ravi K. Garg • Timothy W. King • Delora L. Mount

Surgical disease has been estimated to account for 11% of the world's disability-adjusted life-years (DALYs), or years lost to death and disability.¹ An estimated 14 million DALYs are related to congenital anomalies, and 62 million DALYs are caused by traumatic injuries.² In addition, road traffic injuries are a leading cause of death among individuals 10 to 19 years of age, and burn injuries necessitate hospitalization for an estimated 500,000 children each year.^{3,4}

Despite these staggering numbers, approximately 2 to 3 billion people do not have access to basic surgical care.⁵ Furthermore, there is a significant disparity between the availability of surgical services in resource-rich countries and those of resource-poor countries. A review of surgical volume for resource-poor countries, which account for 35% of the world's population, showed that these countries were responsible for only 3.5% of all surgical procedures performed globally.⁶

Surgical outreach has historically been omitted from global health agendas, possibly because the focus has been on communicable diseases.^{7,8} Interestingly, noncommunicable diseases have been shown in several instances to account for a larger burden of disability than communicable diseases.⁹ An increase in the number of disabilities and deaths on the African continent, for example, is related to surgical rather than infectious disease; historically, however, more attention has been given to parasitic, bacterial, and viral diseases.¹⁰

Considering the great volume of surgical disease attributed to congenital, burn, and traumatic bony and soft tissue injuries, plastic surgeons have a significant role to play in global health. However, there is a significant shortage of plastic surgeons in many countries, including Zambia (1 plastic surgeon per 10 million people). Other more populous nations, such as China and India,

have an estimated 3000 qualified plastic surgeons.¹¹ Yet as in wealthy countries, many surgeons in these countries are drawn to urban lifestyles and cosmetic surgery practices.¹¹ Predictably, surgery is often only available to the wealthy, which exacerbates the problem.⁸

Thus there is a tremendous need for interested plastic surgery volunteers to contribute to treating surgical disease in the short term and creating sustainable models for ongoing prevention and care of patients in the long term. Many of the examples in this chapter will focus on the history and evolving models for cleft lip and palate surgical outreach, because this has been the focus of the majority of research in the plastic surgery and global health literature. Nonetheless, pediatric plastic surgeons have an integral role to play in the various disease processes regularly encountered in practice.

GLOBAL HEALTH MODELS

Global health programs have often been distinguished as representing a vertical or horizontal model of health care delivery. *Vertical models* involve the delivery of health services from donors and volunteers without integration into local health systems. *Horizontal models*, on the other hand, involve the provision of health care services through publicly financed health systems and local health care providers.

The concept of horizontal health care delivery was established and advocated for in the World Health Organization (WHO)/United Nations Children's Fund (UNICEF) declaration of Alma Ata in 1978.¹² The declaration of Alma Ata was the first international declaration emphasizing the importance of primary health care for all citizens of all nations. There was a strong emphasis on primary care, the importance of the state in providing health services, and access to and equality of services for all people. Various failures of horizontal initiatives, such as the inability to contain malaria in India in the 1980s, may have encouraged a shift toward predominantly vertical strategies for the delivery of health interventions to underserved populations.¹³ Vertical programs often have more immediate results than horizontal programs, because they do not require working through local government systems and may therefore be more attractive to benefactors.

Although the dichotomy between vertical and horizontal health delivery strategies is often made, a systematic review of global health programs identified that the programs often employ a combination of strategies, some of which are integrated into the local infrastructure and others which are not.¹⁴ Multiple considerations must be addressed in any outreach effort, ranging from financing and revenue generation for a project to administrative planning, priority setting, resource allocation, health service delivery, program monitoring, and patient education.¹⁵ Some of these considerations may not be manageable in a local context given limited resources, whereas other strategies might be entirely possible with local personnel and infrastructure, leading to hybrid programs with a mix of international and local contributions.

In the context of global surgery, a few models have been described that involve varying dependence on both international volunteers and local personnel and resources. Although numerous organizations exist that provide charitable work to underserved areas, it is beyond the scope of this chapter to list them all or define what model these organizations represent. This would be challenging, because the organizational structure and health care delivery model of an organization may evolve over time. In addition, there are often vastly different opinions about what type of model a program represents based on what features of a program are emphasized. Operation Smile, for example, has been described as being organized around short-term medical missions, and it has also been described as promoting sustainability and the development of comprehensive cleft centers.^{16,17}

Rather than categorize all the major plastic surgery outreach programs, we will outline a few basic strategies that describe how a global surgery program may interface with an underserved area. We will also select a few examples of historical and current programs that exemplify certain features of these models, although one could argue that they also share features of other global health models.

Short-Term Surgical Case Performance Model

The short-term model involves surgical teams that make short visits to areas of need and perform a high volume of surgical procedures. The positive aspects of this model are that a large number of children can have surgery performed. The limitations of this model are that these programs do not necessarily establish local strategies for creating sustainable change, such as training local health care providers to perform surgery. Trips are usually brief, lasting a couple of weeks. Although ReSurge International has since changed its approach to have more of a focus on local capacity building, early efforts in the organization's history toward making periodic trips to underserved areas and performing cleft lip and palate, hand, and burn surgeries serve as examples of the short-term surgical trip.¹⁸

Another example is disaster relief in a location afflicted by war or natural disaster. A multidisciplinary team aboard a U.S. Navy ship provided comprehensive services in craniomaxillofacial trauma reconstruction after the 2010 Haiti earthquake.¹⁹ The ship was stationed near Haiti for approximately 2 months, which is longer than the duration of most short-term trips, during which 93 craniofacial reconstructions were performed. More recently, ReSurge has demonstrated that well established surgical teams can provide both long-term care in a region and disaster relief in scenarios such as the Nepal 2015 earthquake.²⁰

Hybrid Model

The hybrid model represents a cooperative partnership between the global health program and local plastic surgeons. The strength of this model is that it strives to deliver sustainable plastic surgery care to the location of interest. The effects of the outreach last well beyond the time frame of the outreach effort because of integration with local surgeons, who receive training to perform subspecialized surgery. Although fewer cases are performed in the immediate setting of a surgical trip, a multiplier effect happens, because local surgeons become trained and empowered to offer services to the community throughout the year. ReSurge similarly serves as an example of the hybrid model, because it has placed increasing emphasis on education and training of local health care providers to foster local plastic surgeon autonomy.¹⁸

SmileTrain also heavily emphasizes the empowerment and training of local health care providers by offering funding and educational resources to existing facilities that have the basic skills and tools but not the resources to expand their cleft outreach efforts.¹⁸ Their educational programs have included symposia, workshops, fellowships, and the use of virtual surgery software and three-dimensional animated videos to help facilitate the training of health care providers worldwide.²¹

The Barsky unit of Vietnam serves as a historical example of how a hybrid model can eventually transition to ownership of an outreach program by local physicians. In the wake of the Vietnam War, Children's Medical Relief International was founded and established a hospital for pediatric surgery in Saigon. Operations were initially performed by international volunteers, who also provided training to Vietnamese surgeons.²² The surgery center, also known as the Barsky unit, was established in 1969 and by the mid-1970s was almost entirely operated by Vietnamese surgeons.¹⁸

Extended Residence Model

In the extended residence model, the plastic surgeon relocates to an underserved area to develop a center of excellence in a resource-poor area. This model helps further the goal of sustainability by integrating the plastic surgeon into the hospital administration and community. As a result, there is ample opportunity for information exchange, continuity of care, and patient follow-up. A limitation of this model is that the plastic surgeon must be willing to leave behind or relocate family for an extended period of time.

Dr. Samuel Noordhoff's extended stay in Taiwan exemplifies this model. He initially moved to Taiwan in 1960 and worked as hospital superintendent at the Mackay Memorial Hospital for 16 years. He then became the chairman of the Department of Plastic Surgery at Chang Gung Memorial Hospital (CGMH) and established the Noordhoff Craniofacial Foundation (NCF), which helped support the development and eventual independence of the Chang Gung Craniofacial Center.²³ The craniofacial center now sends surgical teams to other countries in close collaboration with the NCF to help provide humanitarian care. The center also hosts international visitors and fellows, with the goal of cultivating autonomous care by local health professionals in other underserved regions.²⁴

OUTCOMES AND GLOBAL HEALTH IMPACT

Financial Impact

The United States has been estimated to be responsible for 6000 short-term medical and surgical trips to resource-poor countries each year through a variety of organizations at an estimated total cost of \$250 million. Medical trips are estimated to cost approximately \$3 per patient in contrast to the surgical cost of \$700, which accounts for equipment expenses.²⁵ Although these data do not stratify surgical cost by the type and length of procedure performed, they raise the question of whether surgical outreach trips are cost-effective.

Multiple strategies for determining the cost-effectiveness of plastic surgery outreach missions depend on the concept of the DALY. The number of DALYs related to a disease process refers to the number of years of life lost and the number of years lived disabled as a result of the disease.²⁶ The calculation of cost of an intervention per DALY averted depends on several variables, including costs of the intervention, life expectancy of a population, and possibly on the age of the patient if age weighting is used. With age weighting, greater value is assigned to the middle years of life, when the patient's social and economic importance is assumed to be greater.²⁷

An additional variable that goes into the DALY calculation is the disability weight for a disease process. Disability weights are provided by WHO and estimate the severity of a disease on a scale from 0 (healthy) to 1 (dead).²⁸ For example, the disability weight for untreated tuberculosis in the 0 to 4 age range is 0.294 and for a radius or ulna fracture is 0.180, compared with the disability weight of 0.098 and 0.231 for cleft lip and palate, respectively.²⁹

Once the cost per DALY averted is calculated, various strategies can be used to determine whether a given intervention is cost-effective. One approach is to use static costs as a reference for whether an intervention makes financial sense. In 1993 the World Bank published a range of prices that were considered cost-effective.³⁰ An intervention costing \$25 per DALY averted would be highly cost-effective, and an intervention costing \$50 to \$150 per DALY averted would be cost-effective. Any intervention can be weighed against these figures to estimate its cost-effectiveness.

Another strategy suggested by WHO has been to compare the cost per DALY averted with the gross domestic product (GDP) per capita in a country as a reference indicator of whether the cost to add a year of healthy life to an individual enhances the GDP.³¹ A cost-effective

intervention would be at least one time the GDP per capita, and it may be up to three times the GDP per capita, considering the potential of a healthy individual to contribute to and stimulate the economy. For example, Vietnam's GDP per capita is \$1051, and thus a cost of \$68 per DALY averted for cleft lip and palate repair is highly cost-effective.³²

Given the fact that surgical interventions have not been prioritized at the international level in favor of other public health interventions aimed at infectious disease, another strategy is to compare the cost per DALY averted for a surgical intervention directly to the cost of other well-accepted public health interventions, such as vaccination or tuberculosis screening.³² Comparisons reveal that surgical reconstructions such as cleft lip and palate repair are cheaper than sanitation efforts for diarrheal disease and programs directed at prevention of maternal-fetal HIV transmission.

Identifying the cost per DALY averted is clearly important regardless of the strategy used to define cost-effectiveness. A general range of costs for common surgical procedures performed in low- and middle-income countries has been described as \$70 to \$230 per DALY averted.³³ Further data are available for the cost per DALY averted for cleft lip and palate surgery specifically. A review of expenditures for eight Operation Smile missions in 2008 showed that primary cleft lip and palate repair is cost-effective.³⁴ The analysis in this study focused on equipment and travel expenses and did not include the costs to the patient for travel or to the local hospital for accommodating the team. The authors' calculation of cost per DALY averted incorporated the hypothesis that cleft lip and palate cause lifelong disability. The cost per DALY averted ranged from \$7.36 to \$96.04 (average \$33.94), and when these costs were compared with other public health measures, it was clear that the expenditure per year of disability averted is cost-effective.

A study examining the cost-effectiveness of cleft lip and palate repair in Vietnam not only accounted for supply costs and the costs to the outreach organization, but also the costs for patient transportation, food, lodging, and hospital costs.³² The cost estimated per DALY averted for cleft lip and palate surgery in Vietnam ranged from \$56 to \$97, depending on whether age weighting is used and whether the time spent by visiting Korean surgeons is considered vacation time or lost salary. This cost falls in the range of other public health programs, including HIV/AIDS education, and is more cost-effective than many other public health interventions aimed at family planning and tuberculosis management. Further studies have confirmed that cleft surgery trips are highly cost-effective, with an estimated cost of \$72 to \$134 per DALY averted in outreach efforts by SmileTrain.³⁵

Although studies have assessed the cost-effectiveness of global surgery services, the data on quality of care delivered by both visiting and local surgeons have not been adequately studied. Data are scarce on early and late surgical complications. Residual disability related to an absence of speech therapy for cleft palate patients and occupational therapists for patients with hand and burn injuries has not been well described.³² In addition, data on patients' age of intervention, surgeries they underwent before plastic surgery trips, and related costs and consequences of these interventions deserve further attention.¹⁶

Academic Impact

The potential academic and training benefits of global health trips are to health care providers from both volunteer and recipient countries (Fig. 2-1). Plastic surgery resident volunteers may wish to improve their cultural competency and understanding of other health care models, appreciate the impact of global outreach projects, and have the experience of operating in a setting with limited resources. Local providers in resource-poor areas may want to develop new surgical subspecialty skills, acquire new technologies and resources, and develop collaborations and opportunities for advanced subspecialty training.

Fig. 2-1 Educational exchange is an important aspect of global health initiatives and may occur in many forms. **A**, Nicaraguan and University of Wisconsin (UW) plastic surgery residents work together under close supervision to harvest a rib graft for ear reconstruction. Residents learn by operating with both Nicaraguan and UW faculty and from each other. **B**, A UW faculty member takes a Nicaraguan resident through a cleft procedure with other trainees assisting.

There is increasing interest among surgical residents in the United States in having exposure to surgical volunteerism during training.³⁶ A survey of 55 North American surgery programs revealed that 7 (12%) have formal international rotations for residents, 11 (20%) have health-related partnerships, and 34 (62%) have informal programs.³⁶ Experiences among these programs revealed the importance of finding strategies to balance the experience of North American resident volunteers and local trainees, as well as the importance of adapting the goals of a surgical trip to the specific needs of the local community.

A review of the training experiences of plastic surgery resident volunteers specifically reveals that international volunteerism contributes significantly to their education. Survey data for 19 plastic surgery residents who participated in a surgical outreach trip showed that all residents felt an improved sense of cultural competence, enhanced awareness of the nuances of planning and implementing global surgical outreach, and an improved knowledge of how to correct cleft lip and palate deformities.³⁷ Most respondents also felt that their surgical skills were improved, confidence was gained, and the experience provided the foundation for future outreach to underserved populations. A survey of American plastic surgery residencies offering global health experiences found that 96% of programs endorse these opportunities, particularly because they provide exposure to other training systems and enhance surgical education.³⁸ Programs that were unable to offer global health experiences cited the lack of case accreditation and funding as frequent barriers to these cross-cultural and surgical opportunities. These barriers warrant further attention to improve resident access to global surgery opportunities.

Although there are abundant data demonstrating a benefit of global surgical trips to resident volunteers, no studies were identified that rigorously assess the educational value to local health care providers. The potential value may be not only to local physicians but also to surgical technicians, who can perform simple procedures in areas with a physician shortage. Training nonphysicians to perform specialized surgical procedures is a controversial matter. Some would argue that this hinders the development of high-quality health care among surgical subspecialties and leads to fragmentation of services, with poor monitoring and surveillance. On the other

hand, it may be argued that certain simple procedures, such as splinting a fracture or skin grafting a wound, could be performed by individuals with minimal medical training. For example, studies have shown that midwives and technicians can be trained to provide basic surgical interventions to help expand access to emergency obstetric care.³⁹ In addition, nonphysicians who perform surgical interventions may be more likely to provide long-term care in rural and underserved areas.⁴⁰ The potential training benefits of global surgical trips may extend further to local team members providing speech therapy, orthodontic, and other important ancillary services.

In addition to the direct training benefits of global surgery experiences, the pairing of academic programs from volunteer countries with local communities may enable novel research on the needs of underserved areas and methods of delivering cost-effective interventions. Such research may improve the delivery of effective, sustainable care and impact global health policy.⁴¹ In addition, genetic and epidemiologic studies in underserved areas may foster new strategies for disease prevention.⁴²

A North American academic general surgery program demonstrated that time spent in a resource-poor setting by residents during their research years could help improve the quality of global health outreach.⁴³ Resident volunteers sent to Malawi under the supervision of university and local surgeons assessed the training needs of local providers in Malawi and were able to use their needs assessment to improve the curriculum for training local health providers in surgical specialty care. Resident research was also useful for better defining the surgical needs of the local population and showed that WHO estimates of traumatic injuries overlooked patients situated remotely from the hospital. Patients who died as a result of poor access to immediate trauma care were not incorporated into trauma registries. The role of residents in conducting research used to improve the quality and content of training received by local health care providers demonstrates how academic partnerships may benefit local communities.

Sustainability

Survey results from short-term medical and subspecialty surgical trips suggest that 80% consider themselves to have a collaborative relationship with local health care systems, and 100% have a strategy for resumption of care by another provider in case they are no longer available.²⁵ Although collaboration with local providers is important, developing a sustainable project for an underserved community requires that the project meet several criteria, as outlined by WHO⁴⁴:

- The project is effective.
- The project has longevity.
- The project has high treatment coverage.
- The project is integrated into existing health care services.
- The project is owned by the community.
- The project relies on resources from the community and the government.

Previous concerns have been raised that plastic surgery global outreach trips often focus too much on the number of patients they treat rather than the important role of training local plastic surgeons to provide affordable, quality care.⁴⁵ Furthermore, failure to integrate volunteer services into local systems may result in lack of follow-up on patient complications after a volunteer group has left an area.⁴⁶

A study involving group discussions with medical officers in African countries revealed mixed opinions about international volunteers.⁴⁷ Foreign volunteers were valued for their service to remote areas, their ability to provide organization and motivation to local providers, and their skills in educating and training personnel. However, there was also a perception that surgical trip participants were inexperienced, limited by cultural and language barriers, and did not help strengthen the public health system, therefore limiting their long-term impact.

The importance of transitioning ownership of health systems, including surgical interventions, to local teams cannot be overstated. There are multiple potential reasons, however, why outreach programs have not been successful at integrating their volunteer efforts at the local level. In many scenarios, volunteer groups have found that available staff, training, and resources are inadequate to meet the needs of a community.⁴⁸ Furthermore, donors may be more willing to fund quick, short-term interventions, because long-term changes in another country's governance or resources may be unpredictable. Another reason that integration may be challenging is that many parts of the world have questionable government legitimacy and rebel groups who would see outreach efforts through the government as undermining their cause.⁴⁹

To address some of the limitations to immediate integration of a global health outreach program into underserved areas, the concept of a diagonal model has been proposed that takes advantage of foreign resources while maintaining a vision for long-term integration and capacity building.⁵⁰ In this model, foreign volunteers, money, equipment, research ideas, and surgical interventions are welcomed into a resource-poor area, as long as strategies are found to link these resources to sustainable systems that will be widely accessible. In many ways, the diagonal model describes what many outreach programs have already been trying to do.

Literature published on outreach efforts by Operation Smile provides an example of how over time there has been an increasing commitment to not only provide immediate interventions but also to build local infrastructure for sustainable change in delivery of pediatric plastic surgical care.⁴² Several realizations led to increasing interest in local capacity building. Volunteers were limited, and many children would be left untreated without the expansion of local resources and providers. Mission trips that failed to incorporate local providers would potentially undermine and alienate them. A whole team of personnel, including speech therapists, orthodontists, and pediatricians, would be necessary to provide comprehensive care. Systems would need to be in place to ensure the availability of staff trained in life support to maximize patient safety perioperatively.

The importance of a multidisciplinary team in ensuring a sustainable global outreach program, however, goes beyond the roles of physicians in ensuring a safe perioperative experience for the patient. Social workers and psychologists may play an important role in discussing the implications of a pediatric disease process like cleft lip and palate while allaying fears and providing education to families.⁵¹ A multidisciplinary team may also be able to better address malnourishment in children, which is a frequent finding in resource-poor countries that may contribute to complications with wound healing.⁵²

Furthermore, multidisciplinary teams may help improve patient follow-up, which historically has been poor for patients receiving cleft lip and palate surgery during global surgery trips. A 6- to 9-month follow-up for a global cleft surgery endeavor that performed 4100 operations in 2007 was only 36.7% at selected sites.⁵³ A 1-year follow-up was even lower, at 19.9%, and many pediatric plastic surgeons would argue that the 1-year time point is too early to make an accurate assessment of speech outcomes, facial growth, and aesthetics. Therefore, an outreach team with a nurse coordinator or social worker who can facilitate follow-up or find ways to provide patient transportation would be helpful.

Given the importance of developing a multidisciplinary team with local roots, the promotion of surgical specialty hospitals may be one of the most effective ways to deliver quality surgical care safely and affordably.¹⁶ Research in the United States has shown that surgical outcomes are related not only to surgeon volume but also to hospital volume.⁵⁴ The development of centers of excellence for global pediatric plastic surgery that are staffed and led by local plastic surgeons may help ensure the enduring availability of surgical services to populations in need. Whatever the strategy, there must be a carefully considered plan for the long term in any plastic surgery mission as part of the ethics of global health.⁵⁵

Independence

Evidence exists that pediatric plastic surgery initiatives can take root in underserved areas and become autonomously functioning entities. The common theme to stories of locally established centers becoming independent is a strong, long-term commitment to the community on the part of international collaborators with a significant investment in the training, financing, and resourcing of local plastic surgeons.

A commitment by a Korean initiative called Smile for Children to underserved communities in Vietnam resulted in a partnership in which Vietnamese staff had significant autonomy.³² Initially, surgical trips by Smile for Children were led by a senior Korean surgeon and Korean surgical residents. An emphasis during surgical trips was to include Vietnamese surgeons on the operative team to help them learn operative techniques in cleft lip and palate surgery. Vietnamese surgeons were also sent to Korea for intensive surgical training. The result of this approach was that the Vietnamese group continues to operate year-round and only relies on visits from the Korean group for more complicated cases and ongoing learning opportunities.

The NCF, in partnership with CGMH, has also helped to create self-sufficient cleft programs at the local level and to describe a series of steps for achieving this goal. Ironically enough, the CGMH Cleft and Craniofacial Center (CCC) itself was a product of slow, gradual development. When the CCC began, there was only one plastic surgeon, and there was a lack of trained personnel, funding, and government interest, because the public health focus was on treating infectious disease.⁵⁶ Currently the CCC works in conjunction with the NCF to provide cleft training and outreach to underserved areas and to promote their independence. A key aspect in the development of a multidisciplinary center was the selection of motivated people.

The NCF and CGMH have described a series of developmental stages for the emergence of local cleft programs²⁴:

- Stage 1 involves identifying a country or institution to become involved with the provision of services and selection of key physicians and personnel for further training.
- Stage 2 involves providing further training to key physicians and personnel. CGMH reports training 92 “seed” physicians and personnel from 12 countries from 2000 to 2008.
- Stage 3 involves establishing a local cleft center with details decided about facilities, staffing, and funding. At this stage it is critical that local health authorities and providers are willing to support the cleft center logistically and financially to increase the likelihood of it becoming independent of foreign support.
- Stage 4 involves establishing a local cleft foundation that is financially capable of supporting not only itself but also of delivering aid and training to other underserved areas.

The NCF and CGMH report that they have helped to establish a local cleft foundation in the Philippines and cleft centers in Cambodia, China, and Indonesia. Although the global health literature often describes outreach efforts from resource-rich to resource-poor countries, autonomously functioning pediatric plastic surgery initiatives may also emerge in resource-poor countries. The GSR Institute of Craniofacial Surgery in Andhra Pradesh, India,⁵⁷ demonstrates that local physicians may develop a subspecialty plastic surgery center with a multidisciplinary team. The founding surgeon was the initial surgeon and administrator on the team and set up the cleft center in an existing hospital that was strategically situated between multiple states with large cleft populations. Additional team members in pediatrics, otolaryngology, speech therapy, neurosurgery, orthodontics, and dentistry were recruited in addition to a core group of nurses. Ultimately, the craniofacial institute became an independent center, relying on support from foreign and domestic funding sources and providing transportation, surgery, and nutritional counseling for many patients.

WORLD HEALTH ORGANIZATION DISEASE CONTROL PRIORITIES

The majority of global surgery outreach has been led by small groups, academic centers, and non-governmental organizations, and only recently has WHO formally recognized the important role of surgery in public health at an international level.⁵⁸ Although grassroots initiatives and efforts made by motivated volunteers are invaluable, global leadership in defining disease control priorities is important for raising awareness of the unmet surgical needs of resource-poor countries and garnering financial, legislative, academic, and public health resources that can help facilitate change.⁵⁹

WHO is well suited to bring surgical care to the global agenda. As an agency of the United Nations assigned the task of coordinating and promoting international public health, WHO has the ability to establish policies and coordinate resources from its 194 member states and outside funding mechanisms that may bring about widespread change.⁶⁰ WHO, in collaboration with other major entities, including the World Bank, Fogarty International Center, and Gates Foundation, published the second edition of *Disease Control Priorities in Developing Countries* in 2006,² which for the first time had a chapter on surgery. Congenital anomalies, including cleft lip and palate, and traumatic injuries, such as fractures and burns, were listed among a group of common surgical conditions responsible for a significant burden of disease.

The burden of surgical disease, of course, goes well beyond pediatric plastic surgery to involve a wide spectrum of acute surgical problems that low- and middle-income countries often lack the resources to address. WHO has tried to intervene through its Emergency and Essential Surgical Care Project.⁶¹ The goal is to engage general physicians, nurses, technicians, and paramedics in basic surgical techniques that can be performed at primary care hospitals to help meet the demand for surgical care. Future policy planning will be critical in defining how training and services are delivered to underserved populations, and pediatric plastic surgeons have an important role in formulating global surgery strategies.

Efforts are already underway to try to determine which surgical needs can most practically be met at a global level when taking into account surgical complexity and necessary resources. Considerations include equipment requirements, procedure complexity, and the need for supportive services, such as a blood bank, pathology laboratory, and intensive care unit. One strategy has been to prioritize surgical conditions by the extent of the public health burden, the availability of a surgical procedure that is highly or moderately successful, and whether the procedure is cost-effective and feasible to promote at a global level.⁶² In this hypothetical scheme, cleft palate repair was assigned a priority of 2, which falls into the intermediate category. Reasoning for categorization of various procedures was not provided, but this may have been related to the requirement for scarce resources, including orthodontics and speech therapy.

Surgery is receiving more attention on the public policy and planning stage than it has ever received before.⁶³ The reality of global surgery is that health for all people must be maximized with limited resources. This is an exciting opportunity for pediatric plastic surgeons to contribute to multidisciplinary discussions about disease pathology with which they are familiar, ranging from trauma to burns and congenital craniofacial and extremity anomalies. By sharing insight into disease management strategies and volunteering plastic surgery knowledge and experience, we can help improve global health.

CONCLUSION

Congenital anomalies, extremity trauma, and burns are among the most common surgical challenges facing resource-poor countries, and plastic surgeons have the knowledge and technical skills to manage many of these problems. Successful global surgery initiatives require that volunteer surgeons not only be well prepared to deliver care, but also find ways to collaborate with local systems. The most successful global surgical programs have enabled a transition of project management and service delivery to local health care providers. Cost analyses suggest that it makes financial sense to pursue global surgery efforts to both improve peoples' quality of life and enhance their productivity and contributions to society. As the challenges of global surgery become prominent on the global health agenda, ongoing research into health care delivery systems, local team building, personnel training, and resource allocation will be fundamental to expanding the availability of global surgical services.

KEY POINTS

- Surgical outreach has historically been omitted from global health agendas, possibly because the focus has been on communicable diseases.
- Pediatric plastic surgeons have an integral role to play in the variety of disease processes regularly encountered in practice.
- Global health programs have often been distinguished as representing a vertical or horizontal model of health care delivery.
- The potential academic and training benefits of global health trips are to health care providers from both volunteer and recipient countries.
- Evidence exists that pediatric plastic surgery initiatives can take root in underserved areas and become autonomously functioning entities.
- The majority of global surgery outreach has been led by small groups, academic centers, and nongovernmental organizations, and only recently has WHO formally recognized the important role of surgery in public health at an international level.

How to Approach, Evaluate, and Treat the Pediatric Patient

Matthew Reed Swelstad • Delora L. Mount

valuation and treatment of children as plastic surgery patients is a rewarding but often exasperating experience, one that can require an exceptional degree of patience. As in pharmacology dogma, children and infants should not be considered merely small adults. Developing a supportive physician-patient relationship with children is not simply a minimalist, scaled-down approach. Although treatment of adults has its own nuances, adult patient care is characterized by mature behavioral styles and advanced knowledge and reasoning capabilities. In addition, most adult patients are capable of self-consent. Children, however, require a more elementary approach to engage and educate them concerning their treatment. Their reasoning capabilities are usually immature, and they lack knowledge of the most general aspects of health care and well-being.

In this chapter we offer one approach to the evaluation and treatment of children. Although a successful physician–pediatric patient relationship is as individual as the provider and the patient, in this chapter we introduce some insights that may be helpful in treating pediatric patients.

THE FAMILY UNIT

The Child's Support Structure

First, the *family unit* must be defined. Treatment of pediatric patients and their families is unique. The family should be treated as a composite unit, which includes the child patient, parents and/or guardians, and sometimes siblings. The physician must also form an individual relationship of trust with the child. Parents and guardians have varying degrees of sophistication and success in coaching children through the medical process. Demonstration of parenting styles with regard

to behavior modification, discipline, and reactions to stressful situations is magnified in the reaction of the child. For instance, most of us have seen supportive and calm parents who were able to assist and guide their child through the discomfort of a needlestick and closure of a laceration, and then encountered other parents who were not able to provide similar support for a minor examination, resulting in extreme distress for all involved. The cooperativeness of the family unit can be extremely mature and is amazingly complex; it changes over time during subsequent visits, family stressors, and with the age of the patient.

Interaction styles and ultimate decisions on recommended care are somewhat dependent on a child's home situation. The primary caregiver during the day may be the mother, father, guardian, or another child care provider, all of whom are involved in the success or failure of a proposed treatment. Unlike adults, children must always rely on someone else (a guardian) for administration of medications, wound checks, care of incisions, dressing changes, positioning, and other restrictions. Responsible (and sometimes irresponsible) family members greatly affect the treatment outcome. Therefore it is imperative that physicians understand the unique family dynamic, the parents' educational and functional level, potential conflicting interests (such as those of siblings), and the living situation to provide the best care. Appreciation of a family resource pool, adjunctive services, and time constraints, particularly in single-caregiver families and those with other children with special needs, must be considered.

A second potentially conflicting factor in pediatric patient care is the socioeconomic status of the family unit. Children make up the largest indigent population in the United States. The largest demographic in Medicaid enrollees are children, and Medicaid served 30 million children in 2014.¹ No other large group of individuals has such a vast potential for disparate care. Numerous additional children qualify for Medicaid but have not been enrolled and are not insured; the U.S. Census Bureau, before implementation of the Affordable Care Act, estimated that this group comprises another 8.2 million children.¹ Children living in poverty and lower socioeconomic conditions have numerous direct issues of concern. In addition to being at higher risk for chronic conditions such as asthma, they are less likely to have appropriate immunizations and well-baby checkups, and their visits to the emergency room are more frequent.²

Potential problems for plastic surgery patients include an inability to purchase dressing supplies (often not covered by medical assistance programs), working-poor parents who cannot afford to take time off from work for the medical care of a sick or postoperative child, and the limited number of providers who will treat uninsured patients or patients receiving medical assistance.

An additional problem of the financially limited population is malnutrition. Improvements in social support and nutritional guidelines in children include the Women, Infants, and Children (WIC) program, Birth to Three programs, the California Children's Act, and individual state-mandated school cafeteria improvements, particularly in providing breakfast and lunch. Although most hungry adults are able to ask for or prepare food for themselves, in an immature child, hunger and malnutrition may more gradually become evident, as demonstrated by wound-healing problems, delayed growth, behavioral issues, and developmental delays. Counterintuitively, lower socioeconomic class is also associated with major increases in the incidence of childhood obesity because of the wide array of inexpensive, high-calorie, processed foods available. Obesity in childhood is linked to early-onset hypertension and type II diabetes mellitus, which affects surgical risk and outcomes.

Cultural Differences

Surgical outcomes are also influenced by the parents' or family unit's religious and ethnic beliefs. Respect for culturally diverse pediatric patients is essential to prevent alienation of these children

and their families and to best serve their needs. Although many religious and culturally diverse populations exist, we will briefly focus on the following four groups: Jehovah's Witness, Hmong, Amish, and American Indian.

Jehovah's Witness Families

The children of Jehovah's Witness families require special consideration. In this unique population blood transfusions are not promoted, and in some cases they are prohibited because of specific beliefs in biblical scripture. Although legal considerations must be met, the prevailing interest in the welfare of the child must be tempered with consideration for parental desires. Conflict with the religious wishes of Jehovah's Witness families may guide parents to decline treatment or seek acceptable (and controversial) alternatives, such as preoperative treatment with erythropoietin for an upcoming operation with a potential for high blood loss.³ Furthermore, some groups do make exceptions for children, allowing Cell Saver autologous transfusions, although this exception is infrequent.⁴ In cases in which a child's life is in danger as a result of massive blood loss, the courts have consistently supported physicians who transfuse without parental consent, siding with the overall outcome of life preservation and protection of the minor child. It is best to have frank pretreatment discussions regarding the family's wishes for transfusion, to consider alternatives, and to enlist legal intervention when necessary.

Hmong Families

Other ethnic groups such as Hmong immigrants have strong beliefs about reliance on traditional Eastern healing and herbal remedies and a general distrust of Western medical practices and surgery. Children may present late with complications or after failure of other methods, as evidenced by delayed presentation of appendicitis with very high rates of perforation in this population.⁵ Traditionally, illnesses in the Hmong culture are divided into spiritual and nonspiritual causes. Nonspiritual causes are thought to include illness from the environment, food, or drink. Spiritual causes include "loss of souls." Souls are believed to govern the body and maintain health. Soul loss can occur as a result of illness or any invasive procedure such as surgery, phlebotomy, or dental fillings. Touching a child's head may also release these good spirits; therefore a friendly pat on the head in this population is discouraged. In the Hmong belief system, shamans have the power to retrieve lost souls and restore health through ancient practices such as pinching, cupping, and coining to draw out fever, relieve headache, and alleviate vomiting. Western medicine providers may inaccurately interpret marks on the skin left by such maneuvers as the result of physical abuse. Loss of souls is thought to occur with surgery by allowing good spirits to leave the body and bad spirits to enter.⁶

The Hmong generally believe in reincarnation. Basically, if a person dies without all anatomic parts intact, in the next life, the person will be born with missing tissues (that is, cleft lip and palate, scars, and other deformities).⁷ Sensitivity and knowledge of these particular practices are essential when providing informed health care to Hmong patients.⁸

Amish Families

The Amish (who call themselves "plain folk" rather than "Amish") have a unique set of cultural beliefs that influences attitudes and utilization of modern medical practices. The Amish are conservative Protestants who strongly believe in pacifism, separation of church and state, peaceful living, and hard manual labor. Advanced education is not routinely encouraged. Hard manual labor jobs and reluctance to use modern conveniences such as electricity, telephones, and gas-powered transportation are typical. Reliance on non-Amish neighbors and friends is often necessary for transportation to health-related appointments. The Amish use home remedies such as mustard pastes and natural homeopathic medicines. Members of this culture routinely refuse social

financial assistance, health care plans, and health maintenance organizations. Decisions regarding medical and surgical treatment in individuals are made by the community leadership, governed by elders and lay leaders within the Amish community. This group routinely pays for care from community funds and will seek professional medical treatment only if the community agrees.^{9,10}

American Indian Families

More than 558 separate American Indian nations and tribes are recognized within the United States. Health care delivery to these unique populations should respect the cultural, historic, genetic, and spiritual diversity within these groups. In addition to increased awareness and sensitivity, health care delivery must also focus on the general health concerns of this population, including the growing epidemic of obesity. For example, in a 2003 survey of 263 Hopi children 6 to 12 years of age, 23% were classified as overweight and 24% as obese.¹¹ Infant mortality rates are also significantly higher in American Indian populations, compared with those of age-matched control groups. Lower socioeconomic status and higher rates of parental alcoholism, fetal alcohol syndrome, diabetes, and unemployment are believed to be contributing factors.^{12,13} The U.S. Census Bureau states that among American Indians and Alaskan Natives, 27% of children are living below the poverty level.¹⁴

Health care delivery can be complicated by subtle social differences. One American Indian physician from South Dakota discussed these cultural differences, specifically, time management and physician-patient eye contact.¹⁵ For example, a common provider misperception is that families and patients are disinterested because of a lack of direct eye contact and tardy arrivals or missed appointments. However, in some Indian cultures, direct eye contact is perceived as a sign of disrespect, and clock-watching is discouraged. Lack of reliable transportation and phone services in some groups compounds this problem.

PARENTAL PERMISSION, ASSENT, AND INFORMED CONSENT

Children do not have the ability to provide informed consent. Informed consent can only be provided by a person with the intellectual capacity and the legal right to do so. A child can, however, offer his or her assent to a procedure or treatment, thereby giving permission. Legally, even though a child gives permission, the responsible adult must provide permission.¹⁶ Obtaining a child's assent is encouraged, because it helps to involve the patient in the process of medical decision-making. A child's ability to provide assent varies, depending on age. The process of obtaining assent also varies, depending on the child's age and ability to comprehend the medical decision-making process. Exceptions to this rule include cases in which a minor is legally emancipated, or when sexually transmitted diseases, pregnancy, or substance abuse is at issue. When parental permission and assent are withheld, and the health of the child is at risk, arbitration or even adjudication may be needed.¹⁶ In acute life-and-death circumstances (such as those requiring blood transfusions in minors of the Jehovah's Witness faith), the courts have supported physician action to prolong the life of the child.

REACTIONS TO TRAUMA, CONGENITAL ANOMALY, OR DISFIGUREMENT

Patient and Parent/Caregiver Anxiety

Many patients in a pediatric plastic surgery practice have significant outward disfigurement and disability. Parents are frequently asked inappropriate and nosy questions about their child's condition by uninformed but well-meaning and curious family members, friends, and strangers. Many parents are quite anxious, distraught, and guilt ridden, somehow believing they are responsible for their child's condition. In addition, in the newborn period, parental depression is common,

with the realization that the infant is not “perfect.” Providers must spend significant time offering compassionate counseling to parents, which often includes meeting with child psychologists or social workers to help with strategies for managing questions and unwanted social attention.^{17,18} Reduction in the parents’ anxiety and guilt will ultimately be reflected in the child’s acceptance of the condition and surgical corrective procedures.

Another interesting phenomenon is the parent’s acceptance of the deformity.¹⁹ In our experience, parents have frequently expressed sadness around the time of a cleft lip repair, stating that they miss the cleft and the baby’s initial appearance. We have also witnessed the extreme of this adjustment, when a mother who did not believe the infant with a newly repaired cleft lip was her son. She was distraught until she heard the familiar cry of the infant and realized that the child was indeed hers.

Some parents are better able than others to handle discussions of medical procedures. For parents who are extremely anxious and queasy, extra time for discussion, a review of realistic postoperative photographs, and meetings with parents who have lived through the experience will provide some of the best solutions.

Preconceived Beliefs About Plastic Surgery

Beliefs about what plastic surgery can accomplish are greatly exaggerated in the popular media, and many parents’ expectations are unrealistic. For example, the most common discussion in the pediatric plastic surgeon’s office is about scars. Parents (and child patients) often have unrealistic concepts of scars, believing that somehow a scar can be completely erased. The reality of scar permanence and the time it takes for complete scar maturation is distressing to a misinformed and immature patient. Considerable time and local scar manipulation can make most scars less noticeable (that is, flat, similar in color to the surrounding skin, and nonirritated or nonpainful), but a scar resulting from reconstruction or traumatic injury will always be present. This fact must be repeatedly reinforced. For example, in our practice, removal of extremely disfiguring darkly pigmented nevi on a child’s face or body has often resulted in postoperative distress with the realization, “There’s a scar!” It is very helpful to revisit the preoperative appearance in photographs to help parents and patients recognize the improvements that have been made. The goals of any surgery should be realistically and repeatedly discussed with the child and parents to prevent an unrealistic expectation of undeliverable results.

Surgery for correction of a cosmetically significant deformity is frequently necessary and is not trivial. Payers, health maintenance organizations, and medical assistance administrations are often confused about this reality. Revision of a significantly asymmetrical cleft lip repair will not improve the function of the lip (usually) or provide a significant functional life-survival benefit, yet that does not mean a revision is an unnecessary procedure. Correction of an obvious deformity is essential for appropriate facial balance and development of appropriate self-perception and psychosocial well-being. This adjustment and the value of surgical correction have been extensively studied in the cleft palate population.²⁰⁻²³ Removal of a disfiguring pigmented nevus on the face of a child may be necessary for optimal socialization, even if removal does not improve the survival of the child. Numerous outcome studies have investigated facial disfigurement and the ability to achieve optimal socioeconomic status, educational level, and well-being.²⁰⁻²³ Many children and adults with disfiguring conditions have overcome this stigma. These patients are exceptional in their abilities, energies, and social support system.

The nature of many plastic surgery procedures for children results in denial of coverage by third-party payers and health maintenance organizations. Insurance companies and governmental medical assistance programs are not currently federally mandated to cover reconstructive procedures for children with deformities resulting from congenital abnormalities, burns, and trauma. Pediatric plastic surgeons must frequently challenge insurance companies’ denials for coverage

of care, placing personal phone calls to medical directors, informing payers about pediatric plastic surgery conditions, and continuously pressuring legislators to pass laws requiring children's deformities to be covered by insurers.²⁴ Pediatric plastic surgeons frequently must educate the public and advocate for their patients who cannot advocate for themselves, both on an individual and a group level.

COMMUNICATION OF NEEDS AND DESIRED OUTCOME

Developmentally appropriate–level discussions regarding specific reconstructive goals are necessary, particularly with older children and teenage patients. A pediatric plastic surgeon may have a particular goal in mind (for example, reducing the size of the nasal tip and bony deviation in a cleft nasal deformity), whereas a teenager may be more focused on the scar. Although it is an unusually sophisticated child or teen who can self-analyze an unacceptable nasal contour, providing a hand mirror during the discussion and acknowledging the child's and the parents' concerns will ensure everyone is in agreement in defining goals for surgery. Preoperative and postoperative photographs of children with similar features are helpful to discuss goals, and particularly to emphasize what can and cannot be accomplished with plastic surgery. Usual postoperative care and expectations should be reviewed in detail. For example, in the case of rhinoplasty, to an adult the idea of postoperative swelling, the presence and sensation of intranasal packing, an expectation of minor bleeding, and the need for a dorsal splint may seem simple concepts, but for a child these events must be explained in detail. In addition, children usually require frequent reassurances and reminders that what they are experiencing is normal.

Surgeons should not take any criticism too personally when children view their early postoperative results. For example, a child who underwent subtotal nasal reconstruction for Binder syndrome (nasomaxillary hypoplasia) was teary and despondent during the unveiling of her newly reconstructed nose. She wailed, "It's so big, it's so big," because she was familiar with only very little nasal contour, and the result was shocking to her. Although similar outbursts can occur with adult patients, usually dissatisfaction or the early reaction to the result is more controlled, subdued, and reasonable. Additional time and consolation is needed for pediatric patients who are shocked or disappointed with the early results. The nasal contour result in the Binder syndrome patient was beautiful, and by her second postoperative visit she had become accustomed to the look and was ecstatic. By her own admission, it was such a drastic change that she was distressed by it.

PSYCHOSOCIAL IMPACT ON SELF-ESTEEM AND WELL-BEING

The current cultural emphasis on outward beauty and aesthetic norms has had a significant impact on children and their perceptions of beauty and acceptance. It is interesting, for example, that as early as 3 years of age, children with cleft lip identify the cleft in self-portraits. The significance of a scar on the upper lip is the same as if daddy wears glasses or mommy has long hair. However, by the time these children are 6 years of age, the cleft lip scar has resulted in psychosocial negative attention and affected their sense of well-being. Numerous potentially abnormal appearances, such as protuberant ears, asymmetrical lips, visible pigmented nevi, and contour irregularities of the craniofacial skeleton are treated within this critical time period, and frequently surgery is performed between kindergarten and first grade to minimize the psychosocial impact of the deformity.²⁵ Children require special attention if they become withdrawn, get into fights, or are wary of school, because they may be receiving negative attention at school or in other social interactions as a result of their deformity. Child psychologists, social workers, clergy, parents, teachers, and other caregivers can help children through the difficulties of growing up with scars and deformities. A close support structure helps children to develop strategies for coping

with negative attention or teasing.²⁶ As part of the history-taking process, the provider should ask whether a child demonstrates aversion to or anxious behavior in school and other social situations. Children who are more mature can be asked directly if they receive negative attention, and their coping strategies can be discussed to uncover problems in this area. A child who experiences significant teasing and negative attention will be forthcoming if the physician has first established a strong and well-developed trust.

ESTABLISHING A PHYSICIAN-PATIENT RELATIONSHIP

The Physician's Demeanor

A pleasant, happy, and somewhat gregarious demeanor rapidly wins over even the most timid and withdrawn patient. Nowhere in medicine is it more important to engage patients with direct eye contact and to speak directly to them (not to the parent or guardian). It is often advantageous to know the latest cartoon characters, movies, and toys. Children will open up if they find the provider interesting and interested in them. Silliness is unnecessary in most interactions but may be necessary with a particularly withdrawn child. For example, one of our colleagues, when meeting with a particularly troublesome child, will make a bet with the child that he has a fish in his pocket. The child usually states, "No you don't." Bantering back and forth leads to our colleague's displaying his fish-shaped writing pen from his pocket, and he continues to make his notations with the fish pen. He even lets the child hold it in the preoperative photographs. This method sets the patient at ease, engages the child with the surgeon, and provides a good laugh during the examination.

In interactions with children the surgeon should never reveal a "bad day" mood, an "I'm running an hour late," hurried behavior, or an "intellectual curiosity" look of consternation or bewilderment when thinking, "Now, how am I going to fix this?" Children directly reflect and communicate their fears, apprehension, and stranger anxiety.

Effective Verbal Communication

Continuing to talk during the examination is crucial. Children become less anxious when they hear the provider's voice, even if the topic is soccer, cartoon characters, or a favorite candy flavor. Surgeons should explain what they are going to look at, why they need to look at it, that it will not hurt, and that they are going to use a flashlight. Waiting for an invitation to examine is counterproductive, but explanations should proceed at the time of the examination. A child who seems timid or scared can be allowed to examine the surgeon first by shining the light in the surgeon's or parent's mouth to understand the examination.

Saying "thank you" to children works wonders (for example, "Thank you for letting me look in your mouth. That was very kind of you. Your tonsils look great today!"). This behavior reinforces a child's involvement and self-consent for care. Appreciation of the child's participation will establish a positive overall tone for the day's visit, benefitting the physician and the child, and will help to ensure a mutually cooperative mood at the next visit.

Child Empowerment in Decisions Regarding Care

With cantankerous children, we often explain what we need to see and then let them choose the order of the examination. Sometimes we examine patients' siblings, parents, and medical students in the room before the patients allow us to examine them. We ask if they would like a special Band-Aid, allow them to choose the color, and ask if they would like cherry- or grape-flavored medicine. By empowering them with even the most trivial of decisions about their care, children think they are active participants in their care and are satisfied to be involved in the team.

White-Coat Anxiety

Children sometimes cringe or cry immediately when they see a physician in a white coat. This phenomenon is not unique to children; we have all heard about hypertension related to “white-coat syndrome.” Children may have anxiety or distress from prior painful interactions (for example, immunizations) and unconsciously relate the white coat to painful stimuli, although this relationship is controversial.²⁷ It is rarely necessary for the physician to remove his or her white coat in the examining room for the patient’s comfort. We prefer not to do this, because we believe the advantage of a white coat, which delineates our role as physicians, is important. However, at our University Hospital, the current pediatric teaching is to go “coatless” to not cause anxiety or stress in the children. We think the white coat symbolizes that the person wearing it is to be trusted, similar to the effect of a police officer’s or firefighter’s uniform. The coat helps a child understand that an examination will occur. It eliminates confusion about being touched by strangers (that is, it is acceptable for a person in a white coat to touch and examine the child, even in a sensitive area, but a stranger without a white coat should be discouraged from touching).

EXAMINATION

Eliciting Cooperation

Children can be notoriously uncooperative with a painful or uncomfortable examination, and often solicitation to proceed is required. Older children can usually understand a simple explanation of why it is important to examine the area. However, reasoning does not work well with a very young or immature child, who may spend endless time asking, “But why?” Offering a reward often succeeds in encouraging cooperation in an immature child. Most pediatric plastic surgeons keep well-supplied award boxes filled with small rewards such as stickers or pencils. Many parents will also help with rewards, such as a promise of lunch at a restaurant, the purchase of ice cream treats, or toys. However, rewarding a child for cooperation does not work well for those who constantly have this type of reward tactic used at home. If parents frequently reward children for every activity, the value of a physician’s reward at the office is significantly diminished. These parents are easy to identify: they usually arrive at the clinic with multiple toys, security objects, and food items. In these instances we reward patients with extra attention and compliments, such as telling them how much we like their shirt, admire their bravery, or like their hairstyle. When praising a child for cooperation, words such as “good” are not used, because they are too general. We tell them we admire how brave they were, how grown-up they behaved, or that we wish all of our patients were like them. Sometimes the best reward is a sincere compliment; even very young children can detect false praise.

Sequence of Examination

The sequence of the examination should be logical, proceeding from least intrusive to most intrusive procedures. For example, if a child has a laceration to the arm, the physician should not start poking the arm right away. The arms are examined while they are outstretched together. The physician then listens to the child’s lungs and heart, and once the child is comfortable with the examination, focuses on the affected area. Children develop a trust in the examiner’s touch during the examination of the nonpainful area. It is sometimes helpful to allow parents or the children themselves to remove bandages. The use of blunt, nonthreatening-appearing bandage scissors and liquid adhesive remover is essential, because it facilitates painless removal of sticky bandages and tape.

Head, Neck, and Oropharynx

In small children and infants, we prefer to perform examinations of the head with the child lying in our lap and looking at mom or dad. Not only does this provide a better perspective for evaluation of head shape anomalies, but it also allows the infant or child to face the parent. Most infants are unable to lift their heads easily; therefore accurate head circumference measurement and clinical examination of shape are enhanced. The oropharynx can be easily examined in this position. The physician can make a game of going upside down, and even if the child becomes unhappy and cries, the view of the intraoral structures is optimal.

Tongue depressors are unnecessary for examining most children. It is always evident when a child has previously gagged on a tongue depressor. Even the use of flavored sticks (grape and cherry) cannot overcome a child's memory of discomfort caused by gagging. If a tongue depressor needs to be used, the child is never allowed to keep it because of the risk of aspiration or injury. Instead, the physician can drop it on the floor and claim "no 5-second rule here," or quickly discard it and refocus the child's attention on another object. Tongue depressors can be very dangerous to young children and should always be carefully discarded.

Children are exquisitely ticklish, so rapid examination of the neck for lymphadenopathy or torticollis should be avoided. Slow and gentle pressure using the fingertips will reduce the tickle discomfort.

Body and Trunk

Most children have little difficulty with body and trunk examinations. Although children in general have less phobic attitudes toward nudity, areas already examined should be shielded or covered. Children deserve no less respect for personal privacy than adults do. In preteen and teenage patients, extra consideration for privacy is warranted. These patients are extremely self-conscious about their bodies.

Hand

Examination of the hand will be thoroughly covered in other chapters, but we will mention here that observation is essential. A child will reach for toys or hold the hand in a cascade posture. Sometimes a game of "Simon Says" can help with diagnosis of hand function. In addition, tendon integrity can be assessed with nonpainful pressure on the upper forearm (far away from the injury in a lacerated finger) and observation of the finger movement and posture. We have found this to be very effective with anxious and uncooperative children in the emergency room.

Other Examination Pearls

Low, Calm Voice

A low, calm voice is essential in an examination and interview. A calm, cool, and collected demeanor will be reflected in the behavior of the patient and parent.

Management of Tantrums

Occasionally, a patient will have an all-out, down on the floor, kicking and screaming tantrum. The physician should calmly restate what will be done and let the parents attend to the child. This method rarely fails. Sometimes everyone in the room needs a time-out—to collect themselves and restart the examination.

CHILD-CENTERED ENVIRONMENT

Visual Stimuli

One of the most elementary comforts for children is being in a child-friendly environment. The offices of most pediatric plastic surgeons are significantly childproof. The office should have obstructions to child's play with computers or instruments, locking drawer systems to eliminate pinched fingers, and light switches and door handles out of reach. For the toddler room, padded corners of tables and desks will reduce the risk of head injury in a walking child.

Children become restless sitting in a small examining room and should be escorted into the room only immediately before the physician enters. In our practice, children and families wait in a large waiting room complete with movies, computers, and toys where they can play and interact with other children. Time waiting in an examining room is minimized. In addition to being childproof, examining rooms with colorful and fun wall hangings, activity centers, mobiles, and toys improve the child's enjoyment of the office visit. Toys in the room should be thoroughly cleaned or replaced between patients and should pose no risk of aspiration (that is, have no small or removable parts).

Children respond favorably to child-sized furniture. They will feel more comfortable if they are able to sit in a child-sized chair or stool rather than awkwardly climbing onto an adult chair with their feet hanging over. Child-sized furniture makes patients feel important and reinforces the perception that the clinic is for them.

Employment of "childcentric" staff is an absolute necessity. Staff members who become annoyed with childish behavior should be reassigned to adult clinics. All staff, including nurses, clerks, physician assistants, and medical assistants, should have a focused interest in the treatment of children.

DAY OF SURGERY

Anxiety Reduction

There is no ideal way to totally eliminate tension and anxiety on the day of surgery. To help, however, a visit by the pediatric plastic surgeon before the patient enters the operating room is essential. Familiar faces, such as nurses from the clinic, will also help to place the entire family group at ease. Before entering the operating suite, most toddlers and children will benefit from some type of mild oral anxiolytic agent.^{28,29} In our institution, the "goofy juice" (usually midazolam and acetaminophen) is well received by children (who are thirsty) and by parents, who are comforted when they see that their child is relaxed before the procedure.³⁰ The preoperative room has child-centered decor, cartoons on the television, and child-appropriate movies.³¹ We believe the presence of the parents on induction of anesthesia is essential to a pleasant operative experience, and only rarely do parents decline.³⁰ Child-life specialists accompany the parent and child into the operating room; they explain the events and are experts in counseling and reducing anxiety in parents and children. They then escort the parents to the waiting room after the child is anesthetized and provide frequent updates from the operating room and supportive care to the parents during the operation.

Intravenous lines are placed, and painful phlebotomy is performed only after the child is asleep and the parents have left the room. Mask induction of anesthesia, which is used in infants, toddlers, and young children, is flavored with cherry, grape, or another flavor. In older children, copious amounts of topical anesthetic cream are used (for example, EMLA) before an intravenous stick. At our institution, intravenous anesthesia is used for older children and teens. There is no age limit for parental presence in the operating room, although most teens self-select to exclude parents from the operating room. Calm and enjoyable family experiences are influenced by

our pediatric anesthesiologists, who often tell bedtime stories to the children as they undergo induction of anesthesia. This sensitive care is appreciated not only by the child but also by the parents, who understand that we are a team dedicated to the care of children.³⁰ Feedback from parents has been positive and is also evidenced in children who must undergo multiple operations and are not anxious at return visits.

POSTOPERATIVE COURSE

Pain and Anxiety Management

When the child arrives in the recovery room and is still sleepy, the parents are escorted in by the child-life specialist. At no time does the child sense that the parents are not present. The child-life specialist remains with the family to explain events and provide support. In the recovery room, pediatric-specialist nursing care is essential. Many children and all infants and toddlers cannot effectively verbally communicate discomfort. Nursing specialists in pediatrics are specially trained to watch for subtle signs of infant and child discomfort and are experts in giving appropriate pain medication, including narcotics. Pediatric nurses facilitate immediate interaction with the parents, including activities such as play or allowing parents to hold the child in a rocking chair. Children who need to be admitted to the hospital after the procedure are housed in a room with childcentric decor with parental rooming-in capability. Support in the preoperative area by trained child-life specialists and play therapy in the postoperative period have been shown to reduce child and parental anxiety and speed recovery.^{32,33}

KEY POINTS

- Children are not just small adults.
- Children account for a disproportionate segment of the indigent population.
- Low socioeconomic class has the potential for a negative impact on the following:
 - Nutritional status
 - Access to general well-child care
 - Access to other health care resources
- Although ethnic and cultural beliefs influence the care of children, health care professionals must understand individual family concerns and background, and decisions must be made that are in the best interests of the child. This may require enlisting an independent child advocate or the court system.
- A child-centered environment, including kid-friendly health care professionals, reduces anxiety in a pediatric patient undergoing surgical treatment.
- Insurance companies and governmental medical assistance programs are currently not federally mandated to cover reconstructive procedures for children with deformities resulting from congenital abnormalities, burns, and trauma.

Ethical Issues in Pediatric Plastic Surgery

John A. Persing • Elizabeth G. Zellner

Although technical skill and proficiency are key qualities of a successful surgeon, the choice of when to operate, and perhaps more important, when *not* to operate, is one of the most critical decisions that a surgeon ultimately makes. Virtually all plastic surgeons, along with the rest of our medical colleagues, took some iteration of the Hippocratic Oath on graduation from medical school. Although passages regarding not “cutting for stone” have largely become historical curiosities, most of us remember the promise to “first do no harm.” Ironically, this phrase was not part of the original Hippocratic Oath, but rather is attributed to Thomas Inman, a nineteenth century surgeon.¹

This key medical premise is inherently challenged by surgical procedures, including those in plastic surgery. As with any surgery, there is a period of potential perioperative “harm” done to patients as a result of surgical trauma. When this harm is done to remove a cancerous tumor or restore a working limb, the temporary pain and discomfort of the intervention are quickly discounted as necessary and unavoidable. However, when the desired change is not a lifesaving procedure but rather a functional or cosmetic improvement, the issue becomes less distinct. Although every plastic surgeon strives to be technically capable and well informed and to perform procedures safely, no surgical intervention is without some risks. Even benign procedures can, in special circumstances, be lethal.

In this chapter we provide a basic framework of the ethical issues inherent to medical practices and to identify some challenges unique to pediatric plastic surgery. As technology and societal expectations continuously evolve, only a sound adherence to ethical principles and sincere attempts to work toward patients’ best interests can truly guide a surgeon through unique and often ethically complex dilemmas.

The American Board of Medical Specialties identifies six core competencies for all practicing physicians to learn and master during training: patient care, medical knowledge, interpersonal and communication skills, professionalism, systems-based practice, and practice-based learning and improvement. Although much work is done on teaching the other core competencies, a recent search turned up only two articles within the plastic surgery literature that discussed training future surgeons in professionalism in a formal manner despite the fact that many plastic surgeons face complex ethical questions every day.² Chung et al³ searched the literature for any papers on ethical issues and found only 110 articles out of more than 100,000 searched that focused on ethical principles. Of these, only 40 represented original research. They also saw a heavy bias toward a focus on patient autonomy and beneficence versus the other main principles of nonmaleficence and justice.³

HISTORICAL PERSPECTIVE

Many of the most challenging issues that confront physicians involve how we view the pursuit of new knowledge and at what cost this knowledge may come. Modern medicine has evolved in some ways at the cost of some questionable previous practices: from medieval anatomists stealing cadavers for study, to the terrible atrocities of medical experiments that were conducted within the Nazi concentration camps, to the injustices of the syphilis studies at Tuskegee, Alabama. Through careful self-examination of our actions and duties as physicians, we must come to a point at which the patient-physician relationship remains a bond of trust.

The first mention of an unethical physician comes from ancient Greek mythology, when the renowned physician Asclepius accepted payment for bringing a person back from the dead despite religious and professional admonitions against performing this act. For his hubris, he was punished by being struck dead by a thunderbolt. Despite these regrettable actions, he was later resurrected as a god for political reasons within the Greek polytheistic world.

The Hippocratic Oath followed shortly thereafter in approximately 400 BC. The Oath was part of the Hippocratic Body, written by Hippocrates of Cos or one of his students⁴ (Fig. 4-1). This document emphasizes loyalty to the profession of medicine, doing what is in the best interest of the patient, avoiding harming patients, and an early mention of patient-physician confidenti-

Fig. 4-1 Hippocrates of Cos, creator of the Hippocratic Oath about 400 BC. (Engraving by Peter Paul Rubens, 1638. Courtesy of the National Library of Medicine.)

ality. By affirming a set of ethical principles, the medical guild of ancient Greece set themselves apart from a purely mercantile establishment. From this point onward, a distinction between business and medicine was firmly established.

By the fifth century AD, the first written code of ethics, the *Formula Comitum Archiotorum*,⁵ was published in the Ostrogoth kingdom of Theodoric the Great in what is modern-day Italy. This doctrine focused primarily on the duty physicians had to deepen their knowledge base and share their knowledge and consultations with fellow physicians.⁵ Throughout the medieval period, Muslim, Jewish, and early Catholic scholars commented on the line between religiously acceptable treatment and what the medical profession actually did. Ishaq ibn Ali al-Ruhawi wrote the first book on medical ethics during this time: *Practical Ethics of the Physician*.⁶

In 1794 Thomas Percival,⁷ an English physician and author, published the first modern treatise on the topic: *Medical Ethics; Or, a Code of Institutes and Precepts, Adapted to the Professional Conduct of Physicians and Surgeons*, which he expanded on in 1803 (Fig. 4-2). In this work he asserted the moral authority and independent service of physicians while affirming the physician's duty to care for the sick.⁸

By 1847 the American Medical Association,⁸ coincident with its founding, adopted its first code of medical ethics, borrowing largely from Percival's work. This code has been updated numerous times throughout the years, most recently in 2001, and is available at the AMA website.⁸ Prominent theorist Joseph Fletcher has been cited as founding "situational ethics" in the 1960s and 1970s and was one of the fathers of modern bioethics. He professed that abstract moral laws should accede to whatever seemed most loving in any given situation. He addressed topics ranging from eugenics to abortion and physician-assisted euthanasia, stirring debates that remain active to this day.

In 1979 Beauchamp and Childress published *Principles of Biomedical Ethics*,⁹ which revolutionized the way that most physicians discuss medical ethics today. Their central premise centered around four principles that can be applied in a flexible and balanced manner to answer the many complex ethical questions that arise in modern medicine. These guiding principles are beneficence, nonmaleficence, autonomy, and justice³ (Table 4-1). Unlike other ethical theories, this set of principles was designed specifically to tackle questions in biomedical ethics.

Fig. 4-2 Thomas Percival, creator of the first modern code of medical ethics in 1794.

Table 4-1 Four Main Principles of Medical Ethics as Advocated by Beauchamp and Childress

Ethical Principle	Description	Example in Plastic Surgery
Autonomy	Acknowledge and respect a patient's right to self-choice and self-governance, free from interference of others and from limitations toward making informed decisions.	Cosmetic surgeons have come under scrutiny that some of their advertisements may be deceptive or intended for the solicitation of vulnerable customers; thus receiving full and informed consent from patients about surgical procedures is jeopardized.
Nonmaleficence	"First do no harm." Obligation not to inflict harm or adverse effects to patients as a result of absence of care.	Because all physicians take an oath to "first do no harm," plastic surgery often falls well outside the traditional goals of saving lives, treating diseases, and promoting health.
Beneficence	Obligation to prevent or remove harm while also promoting good by contributing to the welfare and acting in the best interest of the patient.	Many innovative surgical cases are unique, and surgeons are constantly amending procedures to try to find the best ways to achieve optimal results; however, some may have undesirable side effects. In a disease state, potential benefits versus the potential risks are weighed; however, it is often hard to justify whether an elective procedure on a healthy individual is worth the potential risk.
Distributive justice	Distributing benefits, risks, and costs fairly, equitably and appropriately; treating patients with similar cases in a similar manner.	Many Americans are without insurance or have insurance plans that cover very little. Certain reconstructive surgeries and almost all cosmetic procedures are rarely covered and therefore only financially feasible for the affluent.

NONMALEFICENCE

Nonmaleficence is the only one of the four principles mentioned within the classic Hippocratic Oath, and most physicians find it the most memorable. As physicians, we have dedicated our lives to improving human health, and most try to complete this precept without inflicting harm to patients. However, within the realm of surgery, this is inherently somewhat inconsonant, because all surgery begins with physical trauma to the patient. One "harms" in order to cure. One cuts in order to improve.

Surgeons must constantly balance the risks and benefits of surgical intervention. Any ethical physician will not willingly undertake a procedure that he or she does not believe will benefit the patient. However, it is rarely a decision that is so clearcut. When a patient's benefit will be measured in psychological comfort or a reduction in anxiety, it is more difficult for a clinician to quantify that improvement versus the calculated risk. However, even small cutaneous scars have been shown to have significant effects on patients' mental health years later.¹⁰

Occasionally, a plastic surgeon may be asked to perform a procedure about which he or she may not be fully comfortable. Patients, fueled by the intense media fascination with body shape, may sometimes ask for results outside the realm of responsible plastic surgery practice. In these cases, a prudent surgeon balances the expectations of the patient with his or her own moral com-

pass and technical skill set to outline a plan that will please the patient yet still do no harm. In most surgical consultations, all possible alternative interventions, such as psychological counseling and other supportive treatments, should also be reviewed as alternatives to surgical procedures.

Most pediatric plastic surgery is considered reconstructive surgery. Reconstructive surgery differs from cosmetic surgery in that reconstructive surgery seeks to restore an appearance or function that is considered abnormal to normal. By contrast, cosmetic surgery seeks to improve what is considered normal to beautiful, usually adhering to classical ideals of beauty. Some critics argue that cosmetic surgery to enhance a patient's appearance is at the periphery of the realm of medical practice. Seeing no improvement in patients' physical health and the potential for numerous complications, they believe that cosmetic surgery is "a most unusual medical practice,"¹¹ in the sense that it does not cure disease or reduce physical pain and caters to a patient in a sometimes businesslike marketplace. There are certainly some gray areas; however, most ethical plastic surgeons recognize that they frequently are able to help a patient who has either physical or psychological discomfort by addressing the patient's concerns through surgical treatment.

It is important to screen potential patients for possible psychological comorbidities. One can think of this in terms of identifying unrealistic preoccupation with the body part in question, sometimes indicating *body dysmorphic disorder*. In most situations, if the deformity is proportional to the patient's anxiety about it, there is less likelihood of a negative underlying psychological issue. It is also more likely that the plastic surgeon will be able to deliver a result that is pleasing to the patient when both parties understand the concept of incremental improvement: moderate deformity can be made near-normal in appearance, and normal appearance can be aesthetically enhanced to beautiful. However, it is difficult to take a significant deformity and improve it beyond the normal range to beautiful.

At the same time, it is often challenging to make significant changes without tradeoffs in terms of telltale scarring or differences that are socially notable. It is important that all patients, adult and pediatric alike, have realistic expectations and understand and accept the limitations of even today's plastic surgery before any procedure is undertaken.

In pediatric plastic surgery, there is slightly less patient pressure to push aesthetics beyond the limits of what is considered the societal norm. However, parents and some older patients themselves are conflicted about what is considered acceptable in reconstructive surgery when perfect is not achievable. They must be carefully counseled and supported when further surgery will not improve the ultimate result. A prudent surgeon recognizes this and will not be pressured into further futile operations that will not benefit the patient.

BENEFICENCE

Beneficence, the concept of acting in the patient's best interest to do "good" for the patient, naturally arises from the idea of nonmaleficence. This takes the idea of doing no harm to the next level. As a medical practitioner, Childress and Beauchamp argued, it is not enough to merely keep from harming the patient; one must make an effort to actually improve the quality of the patient's life.⁹

However, in plastic surgery, doing "good" can be difficult to quantify. Certainly, improving appearance and self-esteem seems to be a worthy goal. Patients can be in real psychological pain as a result of self-consciousness about their appearance. Studies have shown that physical appearance has an impact on the quality of life; taller individuals, with other variables controlled, make more money, implying greater occupational success.¹² More attractive photographs attached to identical resumes also increase interview rates significantly.¹³ Perhaps, some argue, we should spend our efforts on erasing these biases in society rather than shaping humans to fit them. However, this is easier said than done, because some biases about physical attractiveness are deeply ingrained with basic tenets of survival, such as selecting a mate based on pelvis shape and indicators of fertility.¹⁴

Regardless of these claims, it is increasingly important in plastic and reconstructive surgery to show the value of surgical interventions. Much recent work has been done on patient-reported outcomes data.^{15,16} As we find ways to quantify patient improvement in quality of life and other outcome measures, it becomes easier to validate the good that is being performed in plastic surgery. It also helps clarify ways to further our field so that we are focusing on the interventions that make the most positive difference to patients. In the future, the perspective gained from this research will be invaluable in counseling patients who are contemplating surgical interventions for themselves and their children.

AUTONOMY

Autonomy is one of the most challenging ethical concepts in medicine, and in many ways it is a thoroughly modern concept. In past eras, medicine was practiced with an air of paternalism in which the doctor was the expert who decided the medical course for the patient. However, since the latter half of the twentieth century, emphasis has increasingly been placed on patients being more engaged in determining their own medical care. In this scenario physicians serve more as counselors and guides than as the driving decision-makers of medical care.

In general, regarding competent, mentally sound patients, surgeons provide counsel but ultimately leave it up to the patients to decide which risks they are willing to undertake to obtain the desired benefits. We formalize this calculated risk-taking through the formal process of written informed consent. True informed consent is a difficult concept in and of itself. In theory, patients are presented with all of the possible benefits of a given intervention and are also told of all the possible risks of the procedure. Even without acknowledging the time restraints and educational barriers that exist in any busy clinic, patients often have preconceived notions of what surgery can provide, and their in-depth understanding of subtle medical nuances is limited. The fact that a skin incision always results in a cutaneous scar and therefore is always unavoidable comes as a shock to some patients and their families. The complicated mechanics, wounds, and aftercare of many pediatric procedures can be overwhelming and are often not fully understood by nonmedical parents.

When patients are minors, which by general legal definition is regarded as individuals under 18 years of age, additional ethical challenges are encountered. Children cannot legally consent for themselves, which leaves this burden to their parents. In the case of life-threatening conditions, the choice to pursue surgery may seem obvious to parents. However, when the desired result of the surgery is a change in the patient's physical appearance, the choice can be less clear. No surgical intervention is free of physical pain during recovery, and some larger reconstructive procedures may have a substantial amount of surgical morbidity. The burden of deciding to undergo surgery can often be significantly distressing to parents.

Although minors cannot legally consent, some advocates push for obtaining pediatric assent according to whatever capacity the pediatric patient meets. Medically speaking, children between 0 and 7 years of age are without such capacity and are unable to make any meaningful decisions about their own health. Children between 7 and 18 years of age have developing capacity, and obtaining at least verbal assent from these children can be a valuable endeavor in bonding with the patient and providing a solid framework for moving forward surgically. Minors have capacity when they are considered mature, such as high school seniors over 18 or "emancipated" minors, who have undergone legal separation from their family's legal authority. These young adults will generally also have legal capacity to sign consent forms despite possibly seeing practitioners with their parents. In addition, those over the legal age of majority, with physical or mental disability so severe they cannot care for themselves, remain legal minors under the care of a legal guardian for the course of their lives.¹⁷

In the face of decisions about their child's future—weighing the benefits of a more normal appearance versus the prospect of surgery on an infant or a toddler—parents often hesitate. Although parents have been shown to be motivated by a desire to do what is right for their children, the choice is not always clear regarding whether a particular intervention is going to really improve their child's life¹⁸ (Fig. 4-3). Some parents and former patients have expressed concern about the ultimate motivations for changing the child's appearance. Is the surgery truly to make the child feel better (many of whom are unaware of their differences at the time of surgery) or to make the parents feel better about the child? It is important to recognize the motivations that drive the desire to correct certain congenital abnormalities. A reasonable conception of physically “normal” involves thinking of a bell-shaped curve with respect to normal human differences. Individuals that fall within the majority of the bell curve generally will be perceived as normal, whereas those who are more than standard deviations away from the mean can be easily recognized as “other,” even by small children.¹⁹ The goal of reconstructive plastic surgery is to restore patients closer to the mean to avoid psychosocial stigmatization. Pursuit of further aesthetic improvement beyond the mean to produce psychosocial benefit has not been scientifically validated, and falls within the purview of cosmetic, not reconstructive, surgery.

The onus falls on the medical profession, often plastic surgeons, to provide appropriate guidance and counseling to parents of children with congenital anomalies. For some conditions, there are common positions on whether or not surgery should be undertaken during childhood. For example, a cleft lip should be corrected early to avoid functional and social deficits, whereas asymptomatic cutaneous hemangiomas should generally not be removed while they still have the potential to regress spontaneously. Many of these consensus positions have been solidified only through decades and even centuries of clinical experience and continue to evolve as new knowledge becomes available.

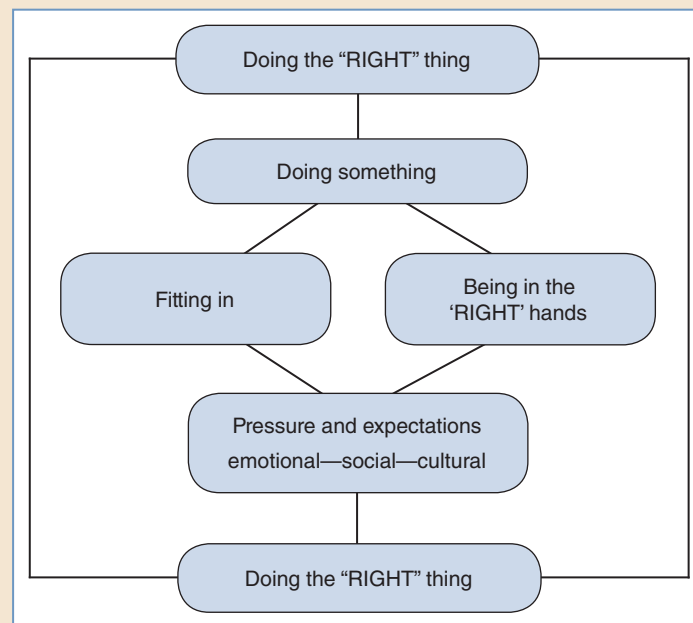

Fig. 4-3 Parental motivations can be complex when making medical decisions for their children.

In addition, organized medicine must continue to push the envelope in research on outcomes to quantify the value of proposed surgical interventions. Although a whole-vault cranioplasty in a child less than 1 year of age may sound too risky for a cosmetic improvement in the baby's head shape, the prospect of improved cognitive abilities and fewer learning disabilities makes this decision much more obvious to parents, who desire the best possible life for their child.²⁰

Although respecting minor patients' autonomy can be difficult under the best of circumstances, family dynamics can further complicate the picture. Legally, any parent with custody of the child can provide consent for surgery. However, at times, various parental interests may not be in agreement. In these situations, which occasionally may pit parent against parent, the clinician's personal sense of ethics and morality may be challenged. It may be helpful to involve the hospital's ethicist before proceeding with surgery in cases of conflicting parental wishes.

Certain special populations may offer further challenges to surgeons. People of the Jehovah's Witness faith usually refuse blood transfusions in the belief that this is in violation of biblical law. Before any surgery, this issue should be fully discussed with the parents, and plans should be made to minimize blood loss and the need for transfusion. In surgical cases with significant blood loss, whether predicted or not, the medical need to transfuse can become obvious. Even in cases in which parents will not consent to transfusion, courts have largely upheld the rights of physicians to transfuse a child (under 18 years of age or a legal minor) to save his or her life. This has been based on the protection of the minor child's life over the parents' religious beliefs. As mentioned in Chapter 1 on evaluating pediatric patients, other cultural differences, such as those found in Hmong, Amish, and American Indian societies, may additionally challenge the preconceived notions of physician ethics. It is important to be aware of culturally sanctioned differences in the perception of medical care and adapt accordingly to best serve these populations.

Finally, it is important to be aware of moments when the child's best interests and those of his or her parents are clearly at odds. Child abuse and neglect can exist, even where one is least likely to suspect such behavior. As physicians serving the pediatric population, plastic surgeons owe it to their patients to be vigilant with regard to possible abuse and to act in the patients' best interest. In any case of suspected maltreatment, physicians are legally required to report their suspicions to the appropriate child protective services.

JUSTICE

Justice is the final concept within the original medical ethics principles. Especially for children, who cannot dictate their family circumstances, it is important that safe and complete medical care be available to all, despite the ability to pay for care. Physicians have not been taught to think regularly of society's needs as a whole when faced with individual patient needs. However, as health care becomes increasingly regulated, this type of thinking and consideration will progressively become more important.

This is especially crucial in various congenital conditions. It has been argued that reconstruction of a hand should be performed while a child is still developing motor control to take advantage of the plasticity of a younger brain and maximize functional outcomes. Soft palate function should be restored before speech development. Given the limited window for intervention in many reconstructive procedures, it is widely regarded as unfair to penalize a child for the family's socioeconomic circumstances. Recognizing this, most states have provided health insurance to cover minors for such procedures.

The extent of *distributive justice* is a much more controversial point. To what extent do hospitals or individual physicians owe care to their specific community in contrast to their obligations to the world at large? Many well-meaning surgical missions have pursued cleft care throughout

the world with the belief that all children deserve a chance at normal appearance and speech, whereas some critics decry the steady stream of surgical procedures and therapeutic interventions undertaken on children who cannot fully realize the benefit of their improved appearance because of developmental or other social influences. The wide spectrum of opinion on this issue provides opportunity for debate in a variety of situations.

Regarding justice, there is the additional complication that the surgeon will likely be rewarded financially for operating. Currently, within most American systems, the more surgery one performs, the greater the reimbursement. This provides a definite conflict of interest when parents are looking to the surgeon for guidance on whether to pursue surgery. The ethical surgeon will not knowingly put his or her own financial gain ahead of the best interests of the patient. The hidden costs to the family unit and the perceived benefit to the patient should be carefully considered before a surgical intervention is undertaken.

Once the decision is made to pursue surgery, the medical team must help the patient and his or her family get the most out of that intervention. Certain supportive therapies, such as home nursing, rehabilitative therapy, and even dressing supplies, must be made readily available to all families if they are needed perioperatively. Social work and supportive hospital resources are important parts of serving vulnerable patients. Comprehensive pediatric plastic surgery centers can be especially valuable in bringing together various specialist and supportive therapies in one place to coordinate care and optimize outcomes.

• • •

Within the concept of these guiding principles, the individual principles are seen as binding unless they conflict with other obligations. In situations in which two of these principles are found to be in conflict, such as patient or family autonomy and nonmaleficence, the principles must be weighed and balanced carefully. In the pediatric population, saving the child's life, ensuring quality of life, and nonmaleficence are generally placed in the highest regard among these concerns.

MODERN CHALLENGES

Technology

As modern medicine continues to advance, new challenges arise in the field of medical ethics. In pediatric plastic surgery, many of these new challenges involve our growing understanding of genetics in various syndromes and conditions. Thus knowledge becomes available at an ever-accelerating rate, and the decisions about how to use such information become a trial ground for ethical debates.

Currently, as a result of technology such as prenatal ultrasonography and genetic testing, conditions as varied as complex trisomies, amniotic band syndromes, and fetal cleft lips and palates can be diagnosed just a few weeks or months into gestation. If parents receive one of these diagnoses, there is often the heart-wrenching option to selectively abort the “damaged” fetus to avoid a long string of difficult surgical and therapeutic interventions. No standards exist to say what makes a fetus “undesirable” or “unfit” enough to be born into this world. From a purely financial standpoint, some children are certainly less expensive to society if they were never to come into existence, but this does not address the child's innate value to their family or society. Decisions about the value of human life vary widely among individuals, and the issue remains politically charged. Is it possible that society could face a system someday in which parents are penalized for knowingly bringing resource-demanding children into the world?²¹ Although no one besides the parents in this situation can fully comprehend or make such a difficult decision,

an ethical and careful genetic counselor is invaluable in these situations.²² Likewise, genetic testing should not be undertaken lightly without some advance awareness by the parents that they may be faced with difficult decisions once they receive this knowledge.²²

Legal ramifications complicate the morality of technologic advances when the possibility of both wrongful birth and wrongful life suits against physicians has become a reality. Craniofacial centers have the opportunity to carefully guide parents through the morass of Internet-based information, genetic uncertainty, and the reality of a given genetic condition. As physicians intimately associated with correcting some of these defects, pediatric plastic surgeons are uniquely positioned to assist parents and society in dealing with these issues.²³ In addition, as public policy and legal standards are set, the medical community is certain, and rightfully so, to be called on as advocates for these patients (or these families).

Clinical Research

Another significant ethical dilemma is the role of pediatric patients in clinical research. Surgeons constantly seek to improve outcomes for all patients, and innovation is a key factor in bettering our field as a whole.²⁴ Despite natural hesitations about “experimenting” on children, careful pediatric research, held to the highest ethical standards, is both permissible and to be encouraged. Without research, one cannot improve outcomes, and if medical professionals fail to pursue advances in medicine, they betray their duty to their patients’ very best interests.^{25,26} Similarly, training of future surgeons must continue within the pediatric population to produce well-trained, clinically competent pediatric plastic surgeons.

Media

Media involvement in all aspects of plastic surgery pervades societal expectations of our field. Originally, plastic surgery evolved as a specialty for the treatment of severe mutilating deformities requiring complex reconstruction after World War I. However, in recent years, because of the distorted portrayals of reality television and an increasingly pervasive celebrity culture, a plastic surgery procedure is sometimes viewed as little more than a commodity—much like a facial or fancy haircut. Popular culture has made it seem as though plastic surgical interventions are both instantaneous, without pain or recovery time, and yield flawless results (as presented with the augmentations of expert makeup and skillful lighting). Television programming of dubious quality, such as public “makeovers,” in which women are offered a complex beauty regimen, including multiple plastic surgery procedures, and then made to compete in a beauty pageant, have served to lower the public perception of the professionalism of plastic surgery.

Regarding pediatric plastic surgery, the media is slightly less intrusive. However, even documentary programs on serious conditions that require reconstructive surgery can be misleading as a result of the careful editing and ultimate results that are shown. Patients are seen to zip from life-threatening deformities to a near-normal appearance in the course of an hour, skipping over the logic of careful medical decisions for the drama of “a good television story” and possibly creating unrealistic expectations for patients and their families.

Although the extreme feature of plastic surgery programming has been toned down somewhat in recent years, the constant barrage of society’s fascination with plastic surgery in the media, both celebrated and decried, continues to pervade popular culture. Patients and their families may come to the doctor’s office with preconceived notions from television and extensive Internet searches about what to expect with surgery. In one study of first-time patients seeking a cosmetic surgery consultation, more than half of the patients considered themselves high-intensity plastic surgery television viewers, most of whom acknowledged that these programs influenced their

decision to pursue surgery.²⁷ Should the surgeon deviate from the expected script, patients can be startled or dismayed, and this can disrupt the trust between the patient and doctor. Physicians should accept researched questions, no matter how apparently misguided, as an opportunity to educate the patient on the reality of surgical options and procedures.

Plastic surgeons also need to be aware of their own presence on the Internet and other advertising avenues. For example, “before and after” photographs can mislead if a balanced set of results is not shown. This is an area carefully monitored by the American Board of Plastic Surgery. Other practitioners may not have as much scrutiny and regulation in their advertising. Plastic surgeons must trust in the quality of their work and honest marketing to ultimately maintain the trust of the public.²⁸

SPECIFIC ETHICAL CHALLENGES

Questions of ethics in plastic surgery are most interesting in concrete examples, where the very real conflicts between some of the various principles can be fully appreciated. Take for example, the very real example of craniopagus (conjoined head) twins who presented to attempt separation at 2 years of age²⁹ (Fig. 4-4). The goal of separation was to improve both quality and quantity of life (craniopagus twins’ life expectancy is approximately 9 years). However, despite meeting the goal of beneficence, the risks of death or severe disability separating the twins were very real. The chances that both twins would survive the surgery were approximately 33%, according to the surgical team. Therefore passing the principle of nonmaleficence is an obvious gray area. With regard to patient autonomy, at 2 years of age the twins had minimal comprehension of the proposed surgery, and this decision was entirely on their parents. The justice of bringing the twins from abroad to the United States, where a very resource-intensive team became dedicated to the surgery, is another unclear area. In addition, the media covered the case relentlessly, bringing both additional acclaim and pressure to the treatment team. All of the four principles of medical ethics, even when examined closely, did not yield an easy solution.²⁹

Another complex ethical dilemma arises in how to treat intersex children with ambiguous genitalia at birth. The initial urge is to make these children appear more “normal.” A large number of endocrine and genetic disorders may lead to ambiguous genitalia at birth or unexpected development at puberty. Children believed to have been female at birth may ultimately prove to have XY chromosomes, or vice versa. Previously, children with clitoromegaly or micropenis may have been treated by clitorrectomy with the good intentions of the child going on to lead a “normal life” as a girl. However, these operations can leave the patients scarred, insensate, and with a

Fig. 4-4 Craniopagus twins from abroad brought to the United States for possible separation.

sense of being violated. At times, a child can be truly confused if the parents attempt to hide such a diagnosis because they believe their child will be confused and hurt by this information. Although the parents facing these issues try to “do what’s best” for their children, their motivations for their child being “normal” may ultimately conflict with their child’s needs. They have been concerned about teasing and difficulty in childhood and have sacrificed their child’s autonomy to protect them from being different (despite evidence that surgical outcomes are better in older children). Increasingly, intersex individuals have been critical of this approach, and many experts now agree that it is best to wait until the child is able to have a say in their own surgical treatment.¹⁹

Children born with congenital hand anomalies can also be a challenge for parents. Even in simple ulnar polydactyly, parents struggle with the decision whether to have a digit tied off, which can cause prolonged pain and an unaesthetic remnant, or to forego correction of the physical anomaly until the patient is old enough to receive anesthesia and have it definitively removed. With complex syndactyly or thumb duplication, the options are more challenging still: it is not always clearcut which fingers should be separated or removed and when to do so. If a patient has a largely functional though disfigured hand, the parents may push for a “normalizing” surgical intervention that may not be in the best functional interests of the child. Surgery may lead to joint stiffness, insensitivity, and discomfort, actually making the hand less useful after surgery. In this case, clinicians may urge parents to take a cautious approach, allowing the hand to develop and grow before any surgical intervention is contemplated.

Not unique to children are questions of composite tissue allograft transplants of “nonessential” organs, such as hands or faces. This raises additional questions about assuming the risks of lifetime immunosuppression in exchange for possible increased quality of life. The first partial face replant, which proved some of the feasibility of an allografted face transplant, was performed after a traumatic threshing machine injury in a 9-year-old child in northern India.³⁰ As composite tissue allograft and immunosuppression regimens become increasingly sophisticated, this may well become a treatment possibility for children with burns or other traumatic injuries.

Similar questionable areas arise when older children begin asking for cosmetic surgery. Teenage years are difficult for any child, but one who looks slightly different from their peers can feel truly alone or ostracized. At 16 years of age, we allow children in many areas of the world to operate motor vehicles. Should they have the same right to decide to reshape their nose at that time? This is largely a decision for the child, his or her parents, and the surgeon to reach together, because there are no legal stipulations on cosmetic surgery for minors.

This is the case for many issues in pediatric plastic surgery, from the morality of overseas surgical missions to the proper surgical decisions in the care of intersex babies born with indeterminate genitalia. Are the surgeries intended to make the child feel better or to make society feel better about the child? Careful decision-making is certainly needed in each unique case. The complexity of medical ethics makes it impossible to establish a straightforward, algorithmic approach to every situation. As such, professionalism and the ethical code of plastic surgery must remain sufficiently robust to face these challenging dilemmas with appropriate knowledge and care.

KEY POINTS

- Medical ethics began as a field in Ancient Greece nearly 2500 years ago.
- The majority of medical ethics writing centers around the four key principles propounded by Beauchamp and Childress in 1979:
 - Beneficence requires acting in the best interest of the patient.
 - Nonmaleficence requires acting in a way to avoid harming the patient.
 - Autonomy involves respecting the patient's individual wishes and personhood with respect to medical decisions affecting their body.
 - Justice refers to the fair and sensible distribution of limited and finite resources in caring for patients and society at large.
- Prenatal diagnoses and genetic testing present new challenges for parents and significant dilemmas for medical ethicists.
- Cosmetic surgery in minors is a controversial topic and should be judged by individual patient and family circumstances.
- Universal solutions for ethical dilemmas in pediatric plastic surgery are rare. Rather, each unique case must be examined for the special unique considerations that will guide recommendations for care.

Anesthesia for Pediatric Plastic Surgery

Franklyn P. Cladis • Martin Beldin Anixter

The primary goal of anesthesia for anesthesiologists, surgeons, and patients is to ensure patient comfort and safety. Events that occur during the period of anesthesia involve a complex interaction of anesthetic technique, surgical technique, and co-existing disease. The anesthetic management of a patient begins with the preoperative visit and can extend well into the postoperative period, including intensive care and pain management. This chapter provides information to assist in the management of all phases of anesthesia care for pediatric plastic surgery patients.

Anesthesia is any technique that allows a patient to withstand a noxious event. The goals of anesthesia are threefold: patient safety, patient comfort, and facilitation of the procedure. Anesthetics combine some or all components of sedation, amnesia, analgesia/anesthesia, and muscle relaxation. They are titrated as needed throughout a procedure and are reversed or allowed to wear off at the completion of the procedure.

Plastic and reconstructive surgery for pediatric patients can involve any part of the body; these children may have a variety of conditions related to existing diseases and syndromes. Safe anesthesia care begins with an understanding of pediatric physiology and development.

DEVELOPMENTAL ANATOMY AND PHYSIOLOGY

Cardiac Physiology

Fetal circulation is characterized by parallel circulation (cardiac output contributes to both pulmonary and systemic perfusion simultaneously, allowing the mixing of oxygenated and deoxygenated blood), whereas in neonates the circulation transitions to series circulation (cardiac output

contributes to either pulmonary or systemic perfusion, with minimal admixture). High pulmonary vascular resistance (PVR) and relatively low systemic vascular resistance also characterize fetal circulation. The foramen ovale and ductus arteriosus allow the shunting of blood around the lungs, with less than 10% of combined ventricular output contributing to pulmonary flow.¹ A series of events occurs at birth that changes fetal circulation into neonatal circulation.

During delivery, PVR decreases and systemic vascular resistance increases, significantly increasing pulmonary blood flow. The increase in systemic vascular resistance occurs as a result of decreased placental blood flow. The onset of spontaneous ventilation creates two factors that cause a precipitous decrease in PVR: a decrease in the mechanical compression of the alveoli and an increase in the partial pressure of oxygen.^{2,3} The increase in partial pressure of oxygen also closes the ductus arteriosus. The changes in pulmonary vascular tone are mediated by biochemical factors, including nitric oxide and prostaglandin. When the PVR decreases, pulmonary blood flow and venous return to the left atrium increase. The increase in left atrial pressure and flow closes the foramen ovale. Over the next few months PVR decreases even further, and the functional closure of the ductus arteriosus and foramen ovale becomes essentially permanent.

In the newborn period, the highly reactive tone of the pulmonary vessels persists. Hypoxemia and tissue acidosis are two important factors that affect PVR. An increase in PVR can lead to right-to-left shunting across the foramen ovale and ductus arteriosus. The persistence of an elevated PVR can lead to further hypoxemia and tissue acidosis. Thus hypoxemia and acidosis can lead to a vicious cycle of increased PVR.

The neonatal myocardium is immature at birth and continues developing postnatally. Many functional differences between the neonatal and adult myocardia are directly related to the immaturity of the neonatal tissue components.⁴ The fetal myocardium has a limited ability to generate the equivalent contractile force, compared with the adult myocardium. The consequence is a reduced capacity to adapt to increases in preload or afterload.^{5,6} Because the neonatal heart has a limited ability to increase stroke volume,⁷ neonates and young infants are poorly tolerant of bradycardia; moreover, significant volume loads may more easily cause ventricular overload and failure.

Respiratory Physiology

A significant difference between neonatal and adult respiration is oxygen consumption. Neonatal oxygen consumption is two to three times greater than that in adults (5 to 8 ml/kg/min versus 2 to 3 ml/kg/min).⁸ This partly accounts for the rapid oxygen desaturation during apnea or hypoventilation.

Neonates and infants also have a higher closing capacity (closing volume plus residual volume) than adolescents and adults. Closing capacity is the lung volume where the collapse of small airways occurs. Neonates have a more compliant chest wall, and a poorly compliant lung. Neonatal/infant lungs are less compliant than adult lungs. Immature lungs in pediatric patients are characterized by small and poorly developed alveoli with thickened walls and decreased elastin.⁹ Elastin provides elasticity to the lung, without which the airways collapse. Because infants (much like older adults) have less elastin, the closing capacity occurs at a larger lung volume in very young and very old individuals.^{9,10} In infants, airway closure can occur before end exhalation (the closing capacity is larger than the functional residual capacity), resulting in atelectasis and right-to-left transpulmonary shunting (Fig. 5-1). An awake, nonanesthetized infant “brakes” exhalation before this point and maintains high respiratory rates to create a dynamic functional residual capacity that is approximately 40% of the total lung capacity, similar to adult values.¹¹ Impairment of this dynamic maintenance of functional residual capacity by anesthesia leads to airway closure, atelectasis, hypoxemia, and right-to-left shunting.

brain.¹⁷⁻¹⁹ In an animal model, exposure to these anesthetic agents resulted in histologic evidence of apoptosis and cognitive deficits.²⁰ These effects occur during a critical period of brain development, and they appear to be dose dependent. The evidence is not as clear in human studies. Large human retrospective database studies demonstrated an association between general anesthesia and learning deficits. Specifically, an association was noted between the number of anesthetics given in patients younger than 4 years of age and learning deficits.²¹ However, twin studies have not demonstrated these problems in learning or in social behavior.^{22,23} A prospective randomized, multicenter trial (GAS Study) showed that 1 hour of sevoflurane in infants having hernia repair did not cause neurocognitive deficits.²⁴ It is still too early to state how much and at what age anesthesia is completely safe. As more data are produced, guidelines and protocols will likely be developed. It may be premature to limit important surgery for children less than 4 years of age because of fear of deleterious neurocognitive effect.

PREOPERATIVE EVALUATION

Performing a thorough history and physical examination, along with judicious use of laboratory evaluations and other tests, can identify and prevent most potential perioperative problems. Coexisting diseases are common in many pediatric patients undergoing surgery and can complicate surgical and anesthetic management. This section is not a comprehensive review of the perioperative management of coexisting disease but attempts to focus on unique aspects as they relate to anesthesia and pediatric plastic surgery patients.

Prematurity

Prematurity is defined as birth before 37 weeks' gestation. It affects all of the organ systems, and the degree of prematurity is a predictor of mortality.²⁵ The immaturity of the respiratory centers is a major cause of morbidity that can extend beyond the neonatal period. Coexisting diseases of prematurity include bronchopulmonary dysplasia, cognitive and sensory impairments, retinopathy of prematurity, and cerebral palsy.

Premature birth, with or without the potential for ventilator-associated injury, is disruptive to the normal development of the lungs. The use of artificial surfactant, prenatal steroids, and lung-protective ventilation strategies ameliorates this effect. Even after weaning from ventilator support, these children can have lifelong decreases in pulmonary function, compared with their age-matched peers.²⁶ This leaves them vulnerable to increased risks of pulmonary complications under anesthesia. This is very important, particularly in young children, in whom respiratory complications of anesthesia are more common.

Cerebral palsy, characterized by motor spasticity, is common in children born prematurely.²⁵ This may require medical treatment (baclofen) or surgical treatment for contractures. Positioning of patients with contractures is very important to prevent intraoperative pressure injuries. These patients may have swallowing disorders and silent aspiration. Seizure disorders can occur in children born prematurely²⁵ and can be treated medically, or in extreme cases, with vagal nerve stimulators.

Sensory and cognitive impairment is common. This can include retinopathy of prematurity, cortical blindness, strabismus, and hearing impairment. Cognitive impairment ranges from severe, affecting all aspects of functioning, to very subtle forms mostly manifesting as attention-deficit disorders or mild problems in school.²⁵

Apnea of Prematurity

Neonates born prematurely who are less than 45 to 60 weeks of postconceptual age (PCA, calculated by the gestational age plus the age of the infant in weeks) may have episodes of apnea severe enough to cause hypoxia and bradycardia.²⁷ Apnea can be precipitated or exacerbated by anesthesia, which is a concern for all prematurely born neonates who are exposed to sedation or general anesthesia before 45 to 60 weeks' PCA.²⁸ The concern that an undetected, untreated apneic event could lead to postoperative cardiorespiratory arrest must be balanced with the need for the patient to eventually return home. The lower the PCA, the greater the risk for postoperative apnea and the longer the duration of disordered breathing postoperatively.²⁹

Other risk factors include anemia (hematocrit lower than 30%) and a history of previous apnea.^{30,31} It is not clear at what PCA a full-term or prematurely born infant ceases to require postoperative monitoring for these events. In general, a PCA of greater than 45 to 50 weeks may qualify an otherwise healthy prematurely born infant to return home the day of surgery. Children's hospitals have predetermined ages at which a prematurely born infant undergoing general anesthesia must be admitted overnight for observation. Our policy at Children's Hospital of Pittsburgh is to admit all prematurely born infants less than 45 weeks' PCA for apnea and bradycardia monitoring. Infants considered at risk for postoperative apnea should be monitored for at least 12 hours, with an additional 12 hours after any apneic episodes.³¹

Neurology

Neurologic abnormalities can alter the anesthetic management of pediatric plastic surgery patients. Many craniofacial abnormalities are associated with increased intracranial pressure (ICP). The characteristic signs and symptoms of increased ICP include headache, irritability, vomiting, papilledema, and hypertension. Bradycardia with hypertension (Cushing's triad when associated with increased ICP) is a late finding and may signal impending herniation. Many of the symptoms of increased ICP may not be present in children with chronically elevated ICP. Papilledema or abnormal visual-evoked potentials may be the only finding on examination.

Patients with increased ICP present several challenges for anesthesiologists. The anesthetic goal is to maintain cerebral perfusion pressure by maintaining mean arterial pressure and minimizing ICP. The risk of aspiration is also higher in patients with acutely elevated ICP and presents a challenge, particularly in patients with a difficult airway. Patients with acutely elevated ICP are typically anesthetized with a rapid-sequence induction using an induction agent that maintains mean arterial pressure and decreases ICP, such as sodium pentothal or etomidate. All of the volatile inhaled anesthetic agents increase ICP in a dose-dependent manner by increasing cerebral blood flow. This has been demonstrated in children even at low concentrations (half the minimum alveolar concentration).³² Techniques to acutely lower ICP include the following:

- Elevating the head of the bed
- Hyperventilation
- Administering barbiturates
- Administering osmotic diuretics (mannitol [Osmitrol]) and loop diuretics (furosemide [Lasix, Lo-Aqua])
- Administering sedation
- Draining cerebrospinal fluid

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) or sleep-disordered breathing is caused by periods of upper airway collapse during normal somatic muscle relaxation during sleep. Frequent and/or prolonged periods of airway collapse can lead to disordered sleep architecture, hypoxia, and hypercarbia. Daytime manifestations in children may not include sleepiness or morning headache, but instead may manifest as irritability and developmental delay. Systemic hypertension, and even pulmonary hypertension, can occur with prolonged exposure to hypoxic events.

Many craniofacial abnormalities and syndromes may be associated with OSA. Tonsillar hypertrophy is one of the most common causes of OSA in children. Obesity is also associated with OSA, and many otherwise “healthy” obese children have undiagnosed sleep apnea. Mechanical factors contributing to sleep-disordered breathing in obese patients include upper airway obstruction, restrictive chest excursion, increased work of breathing, and decreased FRC secondary to adipose tissue. Infants and children with craniofacial anomalies, including micrognathia and midface hypoplasia, can have significant OSA.

The central causes of sleep-disordered breathing occur in patients with prematurity or neurologic abnormalities such as cerebral palsy. Chronic hypoxia/hypercarbia from OSA can lead to central apnea from a reduced respiratory drive and can even increase sensitivity to opioids.^{33,34}

Patients with OSA and sleep-disordered breathing can have disordered breathing while recovering from the sedative effects of anesthesia.^{35,36} Except for the most superficial procedures, patients with severe OSA may be poor candidates for same-day surgery. The intensity of postoperative monitoring depends on coexisting conditions, the severity of OSA/sleep-disordered breathing, and the nature of the operative procedure.

Upper Respiratory Tract Infection

Signs and symptoms of an upper respiratory tract infection may be the most common reason for canceling elective surgery.³⁷ Patients with symptoms of a current or recent upper respiratory tract infection are more prone to developing adverse respiratory events such as laryngospasm, bronchospasm, and oxygen desaturation. These risks are higher with decreasing age, baseline reactive airway disease, prematurity, parental smoking, and surgical or anesthetic manipulation of the airway.³⁷ These children may benefit from having their surgeries postponed for 2 to 6 weeks. The decision to cancel surgery for a child with an upper respiratory tract infection must take into account the urgency of the surgery, the medical condition of the child, and the likelihood that the child will return asymptomatic if the surgery is rescheduled. An otherwise healthy child who is scheduled for a superficial procedure may do quite well with an upper respiratory infection, unlike a child with a coexisting respiratory disease who requires airway manipulation as part of the procedure.

Congenital Heart Disease

Cardiac lesions may accompany craniofacial anomalies. In addition, many nonsyndromic children who are seen for plastic surgery can have coexisting congenital or acquired cardiac disease. As surgical treatment of complex congenital cardiac disease has improved, more patients are now seen with partially or fully palliated lesions.

Initial assessment includes information regarding functional status. In otherwise healthy children with no history of physical limitations (normal bottle feeding or ability to keep up with peers) and normal physical examination results, no further testing is required. In patients with severe or complex cardiac disease, preoperative assessment may require coordinating with the

patient's cardiologist to ensure an uneventful perioperative course. Recent data from electrocardiograms, echocardiograms, and catheterization can provide up-to-date information about rhythm abnormalities, ventricular function, the type and severity of valvular lesions, and the presence and patency of conduits. A complete set of vital signs, including baseline oxygen saturation, should be recorded. This information helps to define operative risk and a plan for intraoperative and postoperative management. Prophylaxis for subacute bacterial endocarditis should be provided as per the American Heart Association guidelines.³⁸

Malignant Hyperthermia

Malignant hyperthermia is triggered by volatile anesthetics and the depolarizing neuromuscular blocker succinylcholine (Anectine and Quelicin). Exposure to these substances causes susceptible patients to have uncontrolled metabolism of muscle energy stores, leading to hypercapnia, tachycardia, hyperthermia, rhabdomyolysis, and death if untreated. Susceptibility to malignant hyperthermia is a genetic disease showing autosomal dominant inheritance in most cases. Some centers use muscle biopsy and halothane-caffeine contracture testing to determine whether older patients or family members are susceptible.³⁹ Unexplained incidents during anesthesia, especially when accompanied by high fever, should be explored both in patients and their family members; when in doubt, a nontriggering anesthetic (devoid of volatile agents and succinylcholine) should be used.

Airway Examination

A thorough examination of the airway may be difficult with extremely young or otherwise uncooperative patients, but it is important for anticipating airway management challenges before they occur. Associated anomalies that can present a challenge include facial and airway features that make mask ventilation and intubation difficult. Features that may predict difficulty with mask ventilation include midface hypoplasia and an enlarged tongue. In addition, a small mandibular space, small jaw opening, decreased translocation, and decreased neck range of motion can be predictive of difficult intubation. Cervical spine fusion, which may occur with Apert syndrome, can make endotracheal intubation even more challenging if neck mobility is decreased. These features may improve after surgical reconstruction, or they may be exacerbated during normal growth of the involved structures or because of scarring.

Laboratory Testing

The yield of preoperative screening tests in otherwise healthy children is low.⁴⁰⁻⁴³ Testing should be focused on assessing the baseline of a preexisting abnormality, particularly if it may be affected by the surgical procedure. For reconstructive surgeries that involve significant blood loss, the child's preoperative hematocrit level and blood type and crossmatch should be determined. In addition, clotting studies should be performed for surgical procedures that involve significant bleeding. These may include a preoperative prothrombin time, partial thromboplastin time, and platelet count. Some centers also perform dynamic clotting studies such as closure time (platelet function) or a thromboelastogram. Patients with OSA may have polysomnography performed preoperatively. The apnea-hypopnea index (AHI) describes the number of apneic and hypopneic events during an hour of sleep. The severity of OSA by this index is shown in Table 5-1. These ranges are different for infants and children than for adults. A range of 0 to 4 may be normal in adults, and a range of up to 20 is considered mild OSA. This is not the case for children.⁴⁴

Table 5-1 Severity of Sleep Apnea in Children

AHI	Severity of OSA
1-5	Mild
6-10	Moderate
>10	Severe

AHI, Apnea-hypopnea index; OSA, obstructive sleep apnea.

Table 5-2 Fasting Guidelines

Substance	Fast Time (hours)
Clear liquids*	2
Breast milk	4
Formula	6
Nonhuman milk†	8

*Clear liquids include fruit juice without pulp, tea (without milk), black coffee, and water.

†Six-hour fast in infants younger than 6 months of age.

Fasting Guidelines

The absence of airway reflexes during general anesthesia places patients at risk for passive regurgitation of stomach contents and subsequent introduction into the lungs. This can lead to aspiration pneumonitis from contact with acidic gastric contents, and possible pneumonia. Risk factors for aspiration include patients being seen on an emergency basis (these patients are more likely to have large volumes of gastric contents) and patients with high disease severity.^{45,46}

Historically, assurance of an “empty stomach” relied on patients being placed on nothing by mouth after midnight the day of their procedure. This can mean periods of fasting from 8 to 16 hours or more, depending on the time of surgery. In addition to being unpleasant, prolonged fasting in patients without access to intravenous fluids or glucose can lead to dehydration and hypoglycemia, especially in very young patients. Liberalization of NPO guidelines (Table 5-2) has increased patient and parental satisfaction without increasing residual gastric volume or aspiration rates.⁴⁷ Exceptions may include patients with reflux or inflammatory bowel disease, who may have normal fluid transit but abnormal solid transit. In particular, solids follow zero-order kinetics: Even small amounts of solid food may pose a significant aspiration risk.⁴⁸

ANESTHETIC MANAGEMENT

Premedication

The prospect of a surgical procedure can produce anxiety for patients of all ages. Going into the unfamiliar environment of an operating room provokes fear of the unknown (“What is going to happen to me? Will it hurt?”) and the known (postoperative pain, needles, and induction). A

Table 5-3 Sedative Premedications

Drug Name	Route and Dose	Benefits and Disadvantages
Midazolam*	PO: 0.5-1 mg/kg IV: 0.05-0.1 mg/kg IM 0.1-0.2 mg/kg Nasal: 0.2 mg/kg	Benefits: Excellent anxiolysis, amnesia, enhances cooperation, onset in 15 min with PO route, 5 min with nasal route Disadvantages: Bitter taste, pain with nasal route, rare paradoxical agitation
Ketamine	PO: 2.5-10 mg/kg IV: 1-2 mg/kg IM: 2-10 mg/kg	Benefits: Rapid onset, excellent sedation, excellent analgesia, mood elevation Disadvantages: Secretions, hallucinations, may lower seizure threshold, rare nausea
Clonidine	PO: 4 µg/kg	Benefits: Antiemetic, analgesic, reduces anesthetic requirement, tasteless, reduces emergence delirium
Dexmedetomidine	PO: 2 µg/g Nasal: 1 µg/kg	Disadvantages: Prolonged onset time (40 min), minimal anxiolytic effect

*Ketamine, clonidine, or dexmedetomidine can be combined with midazolam for an additive effect. The doses can be reduced by 25% to 50% if combination therapy is used.

IM, Intramuscular; IV, intravenous; PO, per os.

special consideration for pediatric patients is separation from their parents or caregivers and application of a mask for inhalation induction of anesthesia. Separation anxiety begins to develop at approximately 7 or 8 months of age.⁴⁹ Separation from a familiar caregiver and introducing a face mask can cause tremendous anxiety and could contribute to increased emergence delirium, increased postoperative pain, and postoperative behavioral changes such as bed-wetting, increased separation anxiety, and nightmares. These postoperative behavioral changes are typically short lived, usually lasting no more than 2 weeks.⁵⁰

One approach for minimizing this trauma is to give a sedative medication before patients are separated from their parents. The goal of this technique is to produce calm, cooperative children who can be taken to the operating room and have an uneventful induction of general anesthesia. The use of a sedative premedication can produce a less anxious induction of anesthesia and may also lower the chances of negative postoperative behavioral changes.⁵⁰ In patients with coexisting diseases, it may be important to balance the risks of an uncooperative child with the risk that sedation may cause airway embarrassment (obstruction resulting from structural abnormalities, bleeding, or foreign bodies) or increased ICP. Other medications used for sedative premedication include ketamine and alpha-2 agonists such as clonidine or dexmedetomidine. These medications are described in Table 5-3.

Another strategy for minimizing separation anxiety and enhancing cooperation is to have a parent present during the induction of anesthesia.^{51,52} If handled correctly, parental presence may be as effective as premedication with midazolam for preventing separation anxiety. However, it is not as effective as midazolam in reducing anxiety associated with the introduction of a face mask.⁵¹ Parental satisfaction is very high when a parent is present during the induction of anesthesia, and most parents would choose to repeat the process in the future.⁵³ However, children who undergo induction of anesthesia in the presence of extremely anxious parents may actually have more anxiety and more negative behavioral changes postoperatively than if anesthesia had been induced in the standard manner.⁵⁴

Monitors

The American Society of Anesthesiologists' standard anesthetic monitors include continuous ECG recording, noninvasive monitoring of blood pressure, and continuous monitoring of oxygenation with pulse oximetry. Continuous end-tidal carbon dioxide monitoring is required if an airway device is used. If a ventilator is in use, a device capable of sounding an audible alarm in the event of an accidental disconnection must be in place. Temperature monitoring must be available to monitor and/or correct intraoperative changes if necessary.⁵⁵

Depending on the surgical procedure and the patient, other monitoring may be necessary. Catheterization of the bladder can provide information regarding volume status, hemoglobinuria, or myoglobinuria and can decompress the bladder during lengthy procedures. Measuring arterial blood pressure may be necessary for patients requiring frequent intraoperative blood sampling (surgeries with significant blood loss), for patients with preexisting or acquired hemodynamic instability requiring beat-to-beat blood pressure assessment, and for patients for whom noninvasive blood pressure measurement is unreliable (such as morbidly obese patients). Central venous pressure monitoring may be necessary for patients in whom vascular access is difficult, when urine output is not a reliable measure of volume status because of renal dysfunction, or during procedures with significant volume shifts (such as third-spacing or bleeding) for which central venous pressure trends may be helpful.

Monitored Anesthesia Care

The definition of *sedation* varies, depending on the specialty. For patients and families, sedation implies anxiolysis and analgesia, with preserved awareness; this may be undesirable for many patients for whom unawareness of the procedure is paramount. For medical personnel, sedation implies minimal perturbation of respiratory drive and airway reflexes, allowing perhaps less hemodynamic and respiratory complications and therefore decreased use of medical resources and faster recovery. In practice, this all depends on the patient, the agents used, and the procedure for which sedation is necessary. All agents have the potential to decrease airway reflexes, despite the preservation of consciousness. The deeper the level of sedation, the greater the possibility of depressed airway reflexes and respiratory and hemodynamic depression. Ideally, the procedure planned should be painless either from the beginning or with judicious application of local anesthesia. In practice, sedation frequently results in a patient who is unresponsive to noxious stimuli. Any sedation procedure should prepare for the possibility of respiratory depression and airway obstruction. The risk of this transition increases when the procedure requires patient immobility, especially with greater levels of noxious stimuli.⁵⁶ Equipment and trained personnel must be available to rescue a patient from the next level of sedation.

General Anesthesia

General anesthesia has the following four characteristics: unconsciousness (asleep), immobilization (akinesis), no pain (anesthesia), and no memory (amnesia). The induction of general anesthesia is the first step in the transition from an awake state to the anesthetized state. This can be accomplished through an inhalation, intramuscular, or intravenous technique. During the induction of general anesthesia, airway management is necessary to prevent hypoxia.

Inhalation (or mask) induction is common for pediatric patients. After the monitors are placed (or during placement with uncooperative patients), a mask connected to the anesthesia machine is placed on the patient, and a mixture of nitrous oxide, oxygen, and a volatile agent (sevoflurane) is given. The inhaled anesthetic agents are delivered to the brain after they are dissolved in the

blood, passing through the alveoli. Many patients become quite claustrophobic from placement of the mask and dislike the pungent odor of the volatile agents. Gentle introduction, scenting of the mask with flavoring, and initiation of odorless nitrous oxide before the introduction of a volatile agent may make this technique less unpleasant.

As a patient inhales the anesthetic agents, an increasing amount becomes dissolved in the blood; this action resembles the administration of a continuous intravenous infusion. The patient transitions from a conscious state to one of excitement and disinhibition, commonly referred to as stage 2. This stage is characterized by increased airway reactivity, and the patient may go into bronchospasm or laryngospasm in this stage with minimal stimulation. If a patient regurgitates stomach contents during this stage, aspiration can occur. After the child is completely anesthetized, noxious stimuli such as placement of an intravenous catheter are well tolerated.

The advantages of inhalation induction are the initial avoidance of needles and the potential for preserving respiration. After a state of general anesthesia is achieved, intravenous access is facilitated both by patient immobility and by the vasodilatory effects of volatile anesthetics. Moreover, it is easier to maintain a difficult airway when a patient continues to breathe spontaneously. Unfortunately, this technique does not prevent regurgitation and aspiration of stomach contents; therefore it is contraindicated in patients with a full stomach. Patients with a mask phobia may not tolerate it well and may prefer the discomfort of a needle rather than have a mask placed on their face.

Rapid induction of general anesthesia can be achieved using intravenous administration of anesthetic agents. For elective procedures, most children and many adolescents fear intravenous injection more than the procedure itself. Reassurance, premedication, preoperative topical anesthetics such as a eutectic mixture of local anesthetics (EMLA), and nitrous oxide may make venipuncture less stressful and painful. The rapid onset of general anesthesia is particularly advantageous for patients with a full stomach who require a surgical procedure, because a secure airway can be established before regurgitation of stomach contents becomes likely; this is known as *rapid sequence induction* (RSI). In addition, intravenous induction of anesthesia is odorless and does not induce claustrophobia. Mask inductions can be difficult with adolescents, because these patients can be uninhibited, strong, and combative during induction.

Airway Management

There are several goals of airway management during general anesthesia. The primary goal is the provision of a patent conduit to the lungs; the airway may become obstructed during unconsciousness, or it may become blocked with stomach contents, blood, or secretions. Another goal is the support of ventilation; hypoventilation and apnea can occur during general anesthesia, and controlled ventilation may be necessary. A third goal is delivery of oxygen and/or anesthetic agents instead of room air. Finally, any airway management strategy must facilitate the surgical procedure being performed.

Natural Airway

The natural airway strategy is appropriate only if the patient does not have a full stomach and does not require positive pressure to maintain a patent airway and adequate ventilation. Nasal or oral airways may assist the patient in maintaining a patent airway with spontaneous ventilation. Supplemental oxygen can be administered, but delivery of gaseous anesthetic agents is unreliable. Infusion of intravenous agents can maintain general anesthesia.

Mask

With a mask, ventilation can be spontaneous or partially or completely controlled. A patent airway can be achieved with gentle positive pressure support in patients who are breathing spontaneously,

or it can be assisted with oral or nasal airways. A tight mask seal allows reliable administration of oxygen and gaseous anesthetic agents. For quick procedures around the face or mouth (such as arch bar removal), a mask can be removed briefly and replaced periodically to deliver more anesthetic. Because the airway is not manipulated, this is the ideal technique for patients with reactive airway disease. However, it does not protect against laryngospasm or regurgitation.

Laryngeal Mask Airway

A laryngeal mask airway (LMA) involves a strategy similar to that used with a normal mask and does not enter the glottis but instead directs air into it. Because it is seated in the oropharynx, past the tongue, it can mechanically create a patent airway in patients with collapse of soft tissues in this area during anesthesia. A proper seal is created that prevents introduction of room air and provides a very reliable delivery of gaseous anesthetics. The patient may be allowed to breathe spontaneously, or ventilation may be controlled. Because of the greater ease of achieving a tight seal and the position of the LMA beyond the soft tissue of the oropharynx, lower peak pressures may be needed to deliver a positive pressure breath than with mask ventilation. Indeed, the mask airway can be used as an emergency airway device for patients who are difficult to ventilate using a mask and in whom intubation is initially unsuccessful.⁵⁶

Once an LMA is placed, ventilation can continue even at a distance from the anesthesiologist. In addition, because less of the face is covered than with mask ventilation, it can be used during procedures for which mask ventilation would likely interfere, such as removal of facial or nasal nevi or dermoid cysts. As with a mask, the airway is minimally manipulated; thus the risk of bronchospasm is lower in patients with reactive airway disease. However, similar to a mask, it does not protect against laryngospasm or regurgitation and is contraindicated in patients with a full stomach.

Endotracheal Tube

An endotracheal tube provides definitive airway management in unconscious patients. It directly enters the trachea, preventing airway obstruction from laryngospasm and minimizing airway soiling. High positive pressures can be delivered with a cuffed endotracheal tube or with an uncuffed tube of appropriate size. Direct stimulation of the trachea can precipitate coughing and bronchospasm under light anesthesia, especially in patients with reactive airway disease. In addition, patients may develop edema at the site of the tube, causing stridor or croup after extubation. An appropriately sized endotracheal tube minimizes this risk. Assessing the degree of air leakage around the tube can also help decrease the risk of tracheal edema and postextubation croup. In general, a leak that is generated at pressures at or below 25 cm H₂O will not cause significant tracheal edema.

Endotracheal tubes come in many sizes and shapes. They have the lowest profile of any airway device and can be placed in the trachea using the nasal or oral route. Placing an endotracheal tube accurately in the trachea usually requires a direct or indirect view of the glottis and surrounding structures. Two exceptions are blind nasal intubation, in which the tube is advanced nasally until breath sounds are heard clearly through it, and the use of a lighted stylet, which illuminates the tip of the endotracheal tube through the sternal notch when it is at the glottis. If any doubt exists about whether a patient can be intubated using a direct view, an alternative technique that is familiar to the anesthesiologist must be immediately available.

Using a direct view, the tube can be seen passing into the larynx looking directly through the patient's mouth. A laryngoscope blade of the appropriate size and shape is used to align the oropharyngeal-laryngeal axis, and the tube can thus be placed through the mouth or nasopharynx directly through the glottis. In some patients this alignment may not be possible because of unfavorable anatomy. At this point the tube can be passed blindly into the glottis if any part

of the larynx is visible as a landmark (posterior arytenoids or epiglottis), or the attempt can be abandoned and another technique used.

Patients with craniofacial anomalies require anesthesia for a variety of procedures, including direct laryngoscopy, tongue lip adhesions, cranial vault reconstructions, and distraction osteogenesis. Some of these patients may have difficult airways, and the anesthesiologist may encounter airway obstruction and a difficult intubation. This can result in intraoperative and postoperative respiratory complications.

Intubation for patients having plastic surgery is performed using a variety of techniques. Some patients may require a nasal intubation (tongue-lip adhesion), but most will need oral intubation. If a patient has been identified as having a difficult airway, specific techniques and equipment may be helpful. The hallmark for managing a known pediatric difficult airway is to maintain spontaneous ventilation. Several airway techniques have been described to assist. These include LMAs (including the air-Q devices),^{57,58} fiberoptic scopes, the GlideScope,⁵⁹ the Shikani scope,⁶⁰ and Airtraq devices.⁶¹ General anesthesia may be induced before securing the airway; however, maintaining spontaneous ventilation is essential. This can be very difficult, and the anesthesia care provider may need to use airway adjuncts such as a two-handed jaw thrust, oropharyngeal airway, nasopharyngeal airway, and LMA. Laryngoscopy should be performed for intubation if the airway remains obstructed despite these maneuvers. If intubation still is not possible, an emergent bronchoscopy with a rigid bronchoscope, performed by Otolaryngology, may secure the airway. An emergent tracheostomy may be considered but is not ideal as an initial rescue maneuver in a pediatric “cannot intubate, cannot ventilate” scenario, because it is time consuming and technically challenging. Extracorporeal membrane oxygenation may be an alternative rescue option in centers where this resource is available.

A paraglossal approach may be more effective than standard laryngoscopy when intubating patients with micrognathia. This technique has been described in patients with Pierre Robin sequence.⁶² It involves placing the laryngoscope in the right corner of the mouth and passing it along the groove between the tongue and the tonsils, using leftward and anterior pressure. The tongue is displaced to the left, and no part of the tongue hangs over the right side of the blade at any time. This shortens the distance to the glottic opening⁶³ (Fig. 5-2).

Fig. 5-2 Paraglossal approach for direct laryngoscopy. The tongue is swept completely to the left.

Other techniques can facilitate intubation in pediatric patients, and they may prove to be useful in pediatric plastic surgery patients. These include the use of flexible fiberoptic scopes, video laryngoscopes (Storz videolaryngoscope, GlideScope), and ultrasonography. A fiberoptic scope can be placed orally through an LMA or nasally to visualize the glottic opening. Nasally, a nasopharyngeal airway can be placed in the opposite naris and used as a conduit to introduce a volatile anesthetic agent and oxygen into the posterior pharynx of the spontaneously breathing patient. The Storz video laryngoscope helped to facilitate intubation in a 9 kg infant with Pierre Robin sequence.⁶⁴ Fladjoe et al⁶⁵ recently compared the GlideScope with direct laryngoscopy in infants and neonates. Although none of these patients had craniofacial anomalies, the GlideScope was effective in patients younger than 1 year of age. The time to obtain the best laryngoscopic view was faster with the GlideScope, compared with direct laryngoscopy with a Miller No. 1 blade. However, the time to pass an endotracheal tube was slower with the GlideScope. The GlideScope has different disposable adapters and per the manufacturer may be used in neonates as small as 1.5 kg.

Patient Positioning

After induction of anesthesia, a patient may need to be repositioned for the procedure. Bony prominences and limbs should be padded and positioned to prevent undue tension and pressure on joints and major nerves. Delicate structures such as eyes, ears, genitals, and fingers should be checked and protected. Patients with proptosis may develop eye injuries resulting from corneal abrasions and globe pressure. The eyes need to be closed or well lubricated, and no pressure should be placed on the globe, especially for patients placed in the prone position.

The airway is a particular concern; it can be dislodged during repositioning and at any time during the procedure if undue tension develops along the anesthesia circuit. Careful taping and positioning of the endotracheal tube and anesthesia circuit decreases but does not eliminate the risk of accidental disconnection. Attention to early signs of disconnection (disconnect alarms, end-tidal carbon dioxide) is vital, because some patient positions (prone) may make resumption of ventilation difficult.

Anesthesia Maintenance

Anesthesia is maintained with inhaled anesthetics, intravenous anesthetics, or both. In patients who are inadequately anesthetized, movement can occur that disrupts the procedure, and awareness is also possible. Total muscle relaxation may be necessary to facilitate surgical exposure.

The depth of anesthesia is assessed using several pathways. Observing heart rate and blood pressure responses to noxious stimuli is helpful but lacks sensitivity⁵⁸ and specificity. Monitoring end-tidal concentrations of inhaled anesthetics is a useful adjunct to monitoring vital signs. These concentrations are equivalent to end-organ concentrations at steady state.

Most patients come to the operating room with a fluid deficit from their preoperative fast. In addition, the anesthesiologist must replace third-space loss, blood loss, urine output, and insensible losses intravenously. In patients with normal renal function who are not on diuretics, urine output can be a good indicator of volume status. Former premature infants and infants less than 2 months of age should have their glucose levels monitored, because their metabolic response to fasting may be inadequate to prevent hypoglycemia.

Blood loss can be assessed in the operating room by observing the suction canisters, weighing the sponges, and using portable quantitative measurements of hemoglobin, such as the HemoCue. Transfusion triggers for anesthetized patients are not identical to those for awake patients. Because of their decreased metabolism, anesthetized patients are typically more tolerant of anemia, and severe anemia in anesthetized patients is invariably asymptomatic and often well tolerated.

For many pediatric patients, a hemoglobin of 7 g/dl can function as a transfusion trigger in those who are hemodynamically and physiologically stable with no significant ongoing hemorrhage.⁶⁶

POSTOPERATIVE CONCERNS

Emergence

When the administration of anesthetic agents ceases, the patient clears them through exhalation, metabolism, or redistribution and begins to emerge. Emergence mirrors induction, with the patient passing first through general anesthesia and then excitement before finally regaining consciousness. All cautions and concerns regarding induction also apply to emergence.

As with induction, manipulating the airway when the patient is inadequately anesthetized (stage 2) can precipitate bronchospasm and/or laryngospasm. For a patient under general anesthesia with an empty stomach and a clear pharynx, it is possible to remove any airway devices and support the airway until the patient is able to do so independently. A patient with a full stomach or a potentially difficult airway must regain airway reflexes before extubation. Signs that a patient has regained airway reflexes include eye opening, purposeful movement, and/or cooperation with simple commands (in older patients); coughing, swallowing, and nonpurposeful movement are not adequate signs.

Recovery

Emergence from anesthesia can extend well into the postoperative period; 30% of deaths attributed to an anesthetic occur immediately postoperatively. Many of the concerns associated with patients in the immediate postoperative period involve the airway. Sedation both from the recent anesthetic and from pain medication given in the recovery room can cause hypoventilation and airway obstruction. These may resolve with supplemental oxygen, stimulation and repositioning, and/or placement of a nasal airway but may require pharmacologic reversal of benzodiazepines or opioids and/or reintubation. Airway obstruction from swelling of the airway and the soft tissues surrounding it can present either in the operating room or immediately thereafter in the recovery room, exacerbating the situation. The airway must be secure before a patient leaves the high-intensity monitoring of the recovery room. Those who still require close observation and frequent interventions may need to be transferred to an intensive care unit.

As patients emerge from anesthesia, they may have nausea and vomiting. Postoperative nausea and vomiting (PONV) is the most common immediate postoperative problem with anesthetized children.^{67,68} In addition to possibly causing dehydration, electrolyte derangements, and surgical site damage from persistent or violent episodes, vomiting can be unpleasant for patients and their parents.⁶⁹ With ambulatory patients, PONV is a common reason for prolonged length of stay or unplanned postoperative hospital admission.⁶⁹⁻⁷⁵ The likelihood of a patient having PONV depends on a combination of patient, surgical, and anesthetic factors.

Intrinsic patient factors such as age, sex, and a history of motion sickness cannot be changed, but this information can help identify patients at risk for PONV. Studies examining PONV tend to find the lowest rates in children up to 3 years of age and show the risk of PONV increasing with age.^{67,76-79} Female sex is not a risk factor in prepubescent children but plays a factor after adolescence.^{77,80} A history of previous PONV or motion sickness is also predictive.⁷⁷ Patients who smoke are at lower risk of PONV.^{80,81} It is not yet known whether secondary smoke exposure decreases risk in a similar manner.

Although some studies have not found the type of surgery to be an important factor with PONV,^{71,81} other studies have shown that ear, nose, and throat surgery, and especially strabismus surgery, pose a greater risk.^{68,77,79} This disagreement may occur because some surgical procedures may be more likely to be associated with other emetogenic risk factors such as postoperative administration of opioids, duration of surgery, and endotracheal intubation.

Many common anesthetic drugs affect the risk of PONV. Halogenated anesthetics increase risk, whereas propofol (Diprivan) decreases risk.⁸⁰⁻⁸² The relationship between nitrous oxide and PONV is not as evident. Some studies show a link,^{81,83} but others do not.^{72,84,85} Vigorous hydration (approximately 30 ml/kg) can decrease the risk of PONV.^{86,87} Finally, although postoperative pain itself can precipitate PONV,⁸⁸ postoperative opioid administration is a risk factor for PONV.^{77,80}

Eberhart et al⁸⁹ created a risk stratification to identify pediatric patients most at risk for PONV. The four risk factors identified are the following:

1. Age older than 3 years
2. Surgery longer than 30 minutes
3. A history of PONV in the patient or family (parent or siblings)
4. Strabismus surgery

The presence of each factor increased the risk by 10%, 30%, 55%, and 70%.

Management strategies for preventing and/or managing PONV depend on a patient's risk for PONV and the potential consequences of PONV in that patient. For patients at low risk, a single intervention or expectant management may be appropriate. High-risk patients may require multiple interventions.^{81,90} In particular, the combination of dexamethasone and serotonin antagonists can be very potent against both early and late PONV.^{72,73} For patients whose treatment has been unsuccessful, treatment with a drug in a different modality or class is indicated.⁹⁰

Some patients develop emergence delirium postoperatively. Emergence delirium is common in preschool-age patients and is characterized by confusion, inconsolability, psychomotor excitement, and dysphoria. This may resolve with administration of sedative or analgesic medications, parental presence, or time. This state is distressing to witness and can lead to patient injury (falling, pulling out intravenous lines, drains, and monitors), caregiver injury, and the need to delay discharge.⁹¹ Awakening to pain may be a risk factor; pretreatment with nonsedating analgesics has decreased the incidence in some series.⁹² Emergence delirium can be treated with a short-acting analgesic such as fentanyl (Sublimaze) if pain is thought to be a contributing factor. The use of dexmedetomidine intraoperatively as prophylaxis or as rescue therapy has become common in pediatric anesthesia. A benzodiazepine such as midazolam may also reduce agitation behaviors. Because patients with emergence delirium may be dangerous to themselves and others, they require intensive nursing care and should not leave the recovery area until their condition resolves.

Several checklists and scoring systems are available to evaluate readiness for discharge from the recovery room. Table 5-4 highlights the clinical features of the Aldrete scoring system.⁹³ The maximum score is 10, and a score of 8 or higher indicates readiness for discharge from the recovery room. In general, satisfactory management of the previously mentioned issues should be sufficient for transfer of patients to a lower intensity of care.

One especially disturbing complication of anesthesia is intraoperative awareness. In adults, the incidence is approximately 0.1% to 0.2%.⁹⁴ The pediatric incidence is difficult to assess because of limited data, but it may be up to fourfold higher.⁹⁵ Anesthesiologists and surgeons alike routinely reassure their patients that they will be unconscious during their procedures. When this expectation is not fulfilled, anxiety and distress result. Consequently, intraoperative awareness has been associated with persistent negative psychological sequelae in adults, including case reports of posttraumatic stress disorder.⁹⁶ However, data do not currently indicate any long-term effects of intraoperative awareness in children.⁹⁵ If a patient or family member describes such an experience, it should be frankly discussed and documented in the chart. The use of a bispectral index to decrease the incidence of intraoperative awareness is intriguing⁹⁷; although data in pediatric patients are sparse, the use of these monitors may be appropriate in patients who are at increased risk for intraoperative awareness. A risk factor for awareness in adults appears to be the use of neuromuscular blocking agents. It is not clear that this is true in pediatric patients. A possible risk factor for pediatric patients is the use of induction rooms.⁹⁸

Table 5-4 The Aldrete Score

Criteria	Score
Able to move four extremities voluntarily	2
Able to move two extremities voluntarily	1
Unable to move extremities voluntarily	0
Able to breathe deeply and cough freely	2
Dyspnea or limited breathing	1
Apneic	0
Blood pressure \pm 20% of baseline	2
Blood pressure \pm 20%-49% of baseline	1
Blood pressure \pm 50% of baseline	0
Fully awake	2
Rousable on calling	1
Not rousable	0
Maintains O ₂ saturation >92% on room air	2
Needs O ₂ to maintain saturation >92%	1
O ₂ saturation <90% with supplemental O ₂	0

The maximum score is 10. A score higher than 8 is required for discharge from the recovery room.

Pain Management

Pediatric patients have pain after many of the plastic surgery procedures. Postoperative pain can range from mild (for example, during arch bar removal or examination under anesthesia) to moderate (after a cleft lip or palate repair) to severe (after rib and iliac crest bone grafting). Intraoperative and postoperative pain can be managed with nonopioid analgesics, opioids, and regional anesthesia. Nonopioid analgesics primarily consist of acetaminophen and NSAIDs. Acetaminophen is well tolerated and can be given orally, rectally and intravenously. NSAIDs include ibuprofen and ketorolac. Ketorolac can be used in infants as young as 2 months.⁹⁹ Infants metabolize the analgesic isomer of ketorolac as fast as or faster than adults.¹⁰⁰

Opioids are a mainstay of pain management. They can be given through a variety of routes (oral, intravenous, neuraxial, intramuscular, and subcutaneous) and are very effective at reducing intraoperative and postoperative pain. Unfortunately, several adverse effects are associated with opioids, including nausea, vomiting, pruritus, constipation, respiratory depression, and rarely, death. Minimizing exposure to opioids is an important aspect of pain control and is a benefit of multimodal analgesia. An effective pain regimen is to provide scheduled (around the clock) nonopioid analgesics like acetaminophen. This will reduce pain scores and opioid consumption and possibly side effects.^{101,102} See Table 5-5 for analgesic medications and dosing.

Codeine has received recent attention because of its relationship with respiratory depression and death in children after tonsillectomy. The FDA placed a second black box warning on codeine in February 2013.¹⁰³⁻¹⁰⁵ Codeine is metabolized to morphine by the hepatic enzyme system CYP2D6. Patients with duplication of CYP2D6 metabolize codeine to significantly more morphine. This higher plasma level of morphine has resulted in significant postoperative complications. Many hospital systems have eliminated codeine from postoperative analgesia protocol for patients undergoing tonsillectomy and other pediatric surgical procedures. Oxycodone is not a prodrug like codeine and does not require metabolism to be analgesic. It is metabolized by CYP3A4, which has significantly fewer polymorphisms. It may be a more consistent and safer alternative.¹⁰⁶

Table 5-5 Analgesic Medications

Medications	Route	Dose
Acetaminophen	PO	15 mg/kg every 6 hr
	Rectal	40 mg/kg load, then 20 mg every 6 hr
	IV	15 mg/kg every 6 hr
Ibuprofen	PO	10 mg/kg every 6 hr
Ketorolac (toradol)	IV	0.5 mg/kg every 6 hr
Morphine	IV	0.02-0.1 mg/kg every 2-4 hr (prn)
Hydromorphone (Dilaudid)	IV	0.005-0.01 mg/kg every 2-4 hr (prn)
Oxycodone	PO	0.1 mg/kg every 3-4 hr (prn)

Multimodal therapy involves combining two or more of these medications. The benefit of multimodal therapy is improved analgesia with reduced side effects.

IV, Intravenous; *PO*, per os; *prn*, as needed (pro re nata).

Regional Techniques

Regional anesthesia can provide insensibility to a wide field and has become a popular technique to combine regional anesthesia with general anesthesia for pediatric plastic surgery patients. It includes neuraxial blocks (caudal and epidural), peripheral nerve blocks, and administration through wound catheters. Analgesia/anesthesia is achieved by placing local anesthetics and/or opioids into the epidural, intrathecal, or perineural space. In infants and children, peripheral and neuraxial analgesia is quite common. Intrathecal or spinal anesthesia is less common and is usually reserved for infants less than 45 weeks' PCA undergoing unilateral inguinal herniorrhaphy. Epidural and peripheral nerve blocks have been described for adult patients having plastic surgery.^{107,108} The benefit appears to be improved analgesia, decreased duration of hospitalization, and increased tissue oxygenation.^{109,110} Epidural anesthesia increases blood flow because of a local anesthetic-induced sympathectomy and may increase graft or flap survival.^{110,111} However, the price for increased blood flow may be a decreased mean arterial pressure, and this may compromise microcirculation to the flap. This phenomenon is more likely to occur in hypovolemic patients.^{112,113}

The reported benefits of the previously mentioned neuraxial blockade have been described for adults, information for pediatric patients is limited. Resting sympathetic vascular tone is diminished in infants, with minimal sympathectomy in those younger than 6 months of age.¹¹⁴ Despite this, epidural analgesia remains a very effective technique for managing acute postoperative pain in pediatric plastic surgery patients. Epidural and caudal blocks are a very effective form of analgesia for procedures involving both lower extremities or the abdomen or chest (Table 5-6). Urinary retention, nausea, and vomiting appear to be more common with neuraxial catheters than with peripheral nerve block catheters.¹¹⁵ Peripheral nerve blocks provide analgesia to a more specific nerve distribution, do not require a Foley catheter, and result in less nausea and vomiting than neuraxial catheters. Patients requiring upper or lower extremity surgery or abdominal or thoracic surgery can have their pain controlled with a peripheral nerve block. Catheters can also be placed, which will allow continuous analgesia for days. There is growing evidence that peripheral nerve catheters can be used to safely provide analgesia in the hospital and at home for ambulatory patients.¹¹⁶ Maximum allowable doses of common local anesthetics are listed in Table 5-7.

The risks of regional anesthesia vary according to the site, but in essence they include failure of the technique, bleeding at the site (such as epidural hematoma), infection, damage to underly-

Table 5-6 Regional Analgesia

Procedure	Block
Bilateral lower extremity reconstruction	Epidural block
Lower extremity flap	Peripheral nerve block (femoral, sciatic, and popliteal)
Upper extremity reconstruction or flap	Peripheral nerve block (interscalene, supraclavicular, infraclavicular, and axillary)
Iliac crest bone grafting	Paravertebral block, wound catheter

Table 5-7 Local Anesthetic Maximum Doses

Medication	Route	Dose
Lidocaine	Subcutaneous, neuraxial, peripheral nerve block	4 mg/kg (maximum dose) 7 mg/kg (maximum dose with epinephrine)
Ropivacaine	Subcutaneous, neuraxial, peripheral nerve block	3 mg/kg (maximum dose)
Bupivacaine	Subcutaneous, neuraxial, peripheral nerve block	3 mg/kg (maximum dose)

ing neural and nonneural structures, and inadvertent intravascular injection of a potentially toxic dose of local anesthetic. In addition, some patients may have physical characteristics, such as spina bifida or infection at the site, that contraindicate certain regional techniques.

Regional blocks are typically placed in anesthetized children. Rarely, the regional block may function as the primary anesthetic with supplemental sedation. For any procedure that uses a regional technique as the primary anesthetic, conversion to general anesthesia or emergent airway management is possible.

SPECIFIC PEDIATRIC PLASTIC SURGERY CONSIDERATIONS

Patients With Craniofacial Anomalies

Craniofacial anomalies are congenital or acquired deformities of the cranial and/or facial skeleton. Although rare, they make up a considerably diverse group of defects. The goal of surgical intervention is to restore both form and function. The classification of craniofacial anomalies is very difficult because of their variability, rarity, degree of severity, and lack of understanding of the etiologic factors and pathogenesis. The Committee on Nomenclature and Classification of Craniofacial Anomalies of the American Cleft Palate-Craniofacial Association¹¹⁷ has proposed the following classification:

1. Clefts
2. Synostosis
3. Hypoplasia
4. Hyperplasia
5. Unclassified

Clefts

Cleft lip is one of the more commonly recognized examples of a craniofacial cleft. However, craniofacial clefts involve a defect of the underlying cranial and/or facial skeleton, as well as the soft tissue envelope, and can involve the entire face. Tessier¹¹⁸ classified these defects by their locations, describing 15 various cleft positions. In this classification, the orbit is the center of the defect from which clefts radiate outward like the spokes of a wheel. *Treacher Collins syndrome*, also known as *mandibulofacial dysostosis*, is an example of a bilateral 6, 7, and 8 craniofacial cleft. Thompson first described Treacher Collins syndrome in 1846, and Treacher Collins later elaborated on the syndrome. It is characterized by poorly developed supraorbital ridges, aplastic/hypoplastic zygomas, ear deformities, cleft palate (in a third of cases), and mandibular and midface hypoplasia. From birth, the adequacy of the airway is the primary concern. The degree of airway obstruction is related to the degree of maxillary and mandibular hypoplasia, choanal atresia, and glossoptosis. Tracheostomy may be required during infancy for those at highest risk of OSA and sudden infant death syndrome.¹¹⁹ Aside from cleft lip and palate repair, major reconstruction typically is timed to occur during childhood or adolescence when the cranioorbitozygomatic bony development is nearly complete.

Anesthetic concerns specific to this syndrome primarily involve the airway. Infants and children with Treacher Collins syndrome may be very difficult or impossible to mask ventilate and/or intubate, and this airway difficulty can increase with age.¹²⁰ Several techniques have been successfully used to safely manage the airway in these infants. The LMA has been used to successfully ventilate a newborn infant with Treacher Collins syndrome for an extended period of time.¹²¹ Direct laryngoscopy, regardless of the blade used, may be difficult. However, the Bullard laryngoscope has been used to successfully intubate a child with Treacher Collins syndrome.¹²² The LMA and the air-Q LMA have also been used successfully to assist intubation of these children.¹²³⁻¹²⁵ Given the potential for difficult mask ventilation and intubation, this population may be best served with a sedated fiberoptic intubation. Another concern for anesthesiologists is protection of the patient's eyes. Because of the presence of maxillary and zygomatic hypoplasia, prone positioning may increase the risk of orbital compression and perioperative blindness. Infants and children with Treacher Collins syndrome can have congenital cardiac defects and require subacute bacterial endocarditis prophylaxis when indicated. Those most affected by upper airway obstruction and OSA may have reduced intraoperative and postoperative opioid requirements.³⁴

Craniosynostosis

Craniosynostosis is defined as an abnormal closure of one or more of the cranial sutures, creating abnormalities in the size and shape of the calvarium, cranial base, and orbits that constitute a diverse group of deformities. Craniosynostosis can also affect brain growth, ICP, and vision, resulting in developmental delay, increased ICP, and visual loss.

Craniosynostosis can occur by itself (simple) or as a major component of a syndrome (complex or syndromic). Six syndromes are associated with craniosynostosis: Apert syndrome, Pfeiffer syndrome, Saethre-Chotzen syndrome, Carpenter syndrome, Crouzon disease (also called *Crouzon syndrome*), and Muenke syndrome. Table 5-8 lists the various syndromes and their associated anomalies and anesthetic concerns. Infants and children with synostosis undergo surgery for cranial vault remodeling to reduce ICP, prevent brain injury, and enhance appearance. Repair of syndromic craniosynostosis may be more complicated and appears to be associated with increased blood loss. The specific cause of the increased bleeding is not known, but it might be related to the length of the operation.¹²⁶

The characteristic features of Apert syndrome include turribrachycephaly (high, steep, flat forehead and occiput), midface hypoplasia, and orbital hypertelorism. Cleft palate occurs in approximately 30% of cases. Choanal atresia and occasionally tracheal stenosis have been reported

Table 5-8 Anesthetic Considerations for Syndromic Craniosynostosis

Syndrome	Sutures	Clinical Features	Anesthetic Issues
Apert	Coronal	<p>HEENT: Turribrachycephaly; midface hypoplasia; orbital hypertelorism; cleft palate in 30%; occasional choanal atresia and tracheal stenosis; airway obstruction</p> <p>Cardiac: Congenital heart disease occurs in 10%; may include VSD, pulmonary stenosis</p> <p>Genitourinary: Hydronephrosis in 3%; cryptorchidism in 4.5%</p> <p>Musculoskeletal: Syndactyly of hands and feet; fusion of digits 2-4; fusion of cervical vertebrae can occur</p> <p>Neurologic: Mental retardation common; may have elevated ICP</p> <p>Dermatologic: Acne vulgaris common</p>	<p>Preoperative laboratory values: Hematocrit, type and screen</p> <p>Airway management: Mask ventilation may be very difficult because of midface hypoplasia, choanal atresia, and tracheal stenosis; intubation may be difficult because of facial anomalies and decreased neck mobility</p> <p>Cardiac: Emphasis on balancing pulmonary and systemic blood flow; “de-air” IV lines; endocarditis prophylaxis</p> <p>Musculoskeletal: Cervical fusion may decrease neck extension; syndactyly may make vascular access difficult</p> <p>Neurologic: Caution with premedication if ICP is elevated</p>
Pfeiffer	Coronal and occasionally sagittal	<p>HEENT: Tower skull; midface hypoplasia; orbital hypertelorism; proptosis; choanal atresia is uncommon</p> <p>Pulmonary: OSA</p> <p>Cardiac: May have cardiac defects</p> <p>Musculoskeletal: Usually mild syndactyly involving broad thumbs and great toes; ankylosis of the elbow occurs rarely; fusion of cervical vertebrae reported</p> <p>Neurologic: Generally normal but mild developmental delay can occur; may have increased ICP</p>	<p>Preoperative laboratory values: Hematocrit, type and screen</p> <p>Airway management: No reported cases of difficult intubation; airway obstruction can occur intraoperatively or postoperatively</p> <p>Cardiac: Emphasis on balancing pulmonary and systemic blood flow; de-air IV lines; endocarditis prophylaxis</p> <p>Musculoskeletal: Cervical fusion may decrease neck extension; syndactyly may make vascular access difficult</p> <p>Neurologic: Caution with premedication if elevated ICP; eyes require protection if ocular proptosis present</p>
Saethre-Chotzen	Coronal and others	<p>HEENT: Brachycephaly; midface hypoplasia; orbital hypertelorism; beaked nose; occasional cleft palate</p> <p>Cardiac: May have cardiac defects</p> <p>Genitourinary: Renal anomalies and cryptorchidism</p> <p>Musculoskeletal: Short stature; mild syndactyly; cervical fusion possible</p> <p>Neurologic: Mild developmental delay; increased ICP is rare</p>	<p>Preoperative laboratory values: As in previous entries</p> <p>Airway management: No reported cases of difficulty with ventilation or intubation; however, patients may be at risk because of the airway and cervical pathology</p> <p>Musculoskeletal: Cervical fusion may decrease neck extension; syndactyly may make vascular access difficult</p> <p>Neurologic: Premedicate cautiously if ICP is elevated</p>
Carpenter	Coronal and others	<p>HEENT: Tower skull; downthrust eyes; orbital hypertelorism; low set ears; small mandible</p> <p>Cardiac: Cardiac defects common (VSD, ASD)</p> <p>Genitourinary: Hypogonadism</p> <p>Musculoskeletal: Syndactyly of hands and feet</p> <p>Neurologic: Developmental delay common but variable; may have increased ICP</p> <p>Other: Obesity</p>	<p>Preoperative laboratory values: As in previous entries</p> <p>Airway management: Small mandible may make intubation difficult; obesity may make ventilation difficult</p> <p>Musculoskeletal: Syndactyly may make IV access difficult</p> <p>Neurologic: Premedicate cautiously if ICP is elevated</p>

ASD, Atrial septal defect; HEENT, head, ears, eyes, nose, throat; ICP, intracranial pressure; OSA, obstructive sleep apnea; VSD, ventricular septal defect.

Syndrome	Sutures	Clinical Features	Anesthetic Issues
Crouzon	Coronal, lambdoid, and others	HEENT: Frontal bossing; tower skull; midface hypoplasia; beaked nose; hypertelorism; ocular proptosis; airway obstruction can occur Neurologic: Occasional mild developmental delay; may have increased ICP	Preoperative laboratory values: As in previous entries Airway management: Intubation may be difficult; may have airway obstruction during awake or sleep states; premedicate cautiously Neurologic: Premedicate cautiously if ICP is elevated; eyes require protection if ocular proptosis is present

HEENT, head, ears, eyes, nose, throat; ICP, intracranial pressure.

and can cause airway obstruction. Congenital cardiac disease is one of the more common associated visceral anomalies, occurring in approximately 10% of cases. Genitourinary anomalies (such as hydronephrosis and cryptorchidism) also occur in 10% of patients with Apert syndrome.¹²⁷ Severe craniosynostosis can result in increased ICP and, if uncorrected, developmental delay. Syndactyly of the hands and feet is often present, with fusion of digits 2 to 4, which can make intravenous access difficult. Cervical spine fusion has been reported¹²⁸; however, many children with Apert syndrome have been intubated successfully. In some cases suboptimal laryngoscopic views secondary to abnormal anatomy may require flexible fiberoptic intubation. The LMA may also be a reasonable adjunct for patients in whom intubation or ventilation of the lungs proves difficult. The air-Q LMA has been used as a conduit for intubation in infants and children with Apert syndrome.¹²⁹ The clinical features and anesthetic implications of Apert syndrome and the other acrocephalosyndactyly syndromes are presented in Table 5-8.

Unlike Apert syndrome, the other acrocephalosyndactyly syndromes are not typically associated with difficult airways. However, midface hypoplasia is common in these infants and may cause significant upper airway obstruction intraoperatively and postoperatively.¹³⁰ Crouzon disease, also called *craniofacial dysostosis*, is part of syndromic craniosynostosis. Infants with Crouzon disease have craniofacial anomalies without visceral or extremity involvement. The anomalies can result in significant airway obstruction that may require early tracheostomy. Table 5-8 outlines the main clinical features and anesthetic issues. During infancy, these patients undergo tracheostomy and/or cranial vault remodeling.

Hypoplasia

Hypoplasia of the craniofacial skeleton is a category of craniofacial anomalies characterized by hypoplasia or atrophy of a portion of the craniofacial soft tissue and skeleton. Pierre Robin sequence and hemifacial microsomia (including Goldenhar syndrome) are examples of these anomalies.

Pierre Robin sequence is characterized by retrognathia, glossoptosis (tongue falling to the back of the throat), and airway obstruction and probably occurs as a result of a fixed fetal position in utero that inhibits mandibular growth. Airway management of infants with Pierre Robin sequence can be very challenging because of difficulty with mask ventilation and intubation. Laryngeal masks have been successfully used to ventilate and assist in intubating these patients.^{57,58} Nasal intubation with a flexible fiberoptic scope has also been described.^{131,132} Direct laryngoscopy performed with a paraglossal approach can be very helpful in patients with small mandibles. This technique was described in infants with Pierre Robin sequence and was successful in five of the

six patients. The technique is described in the Airway Management section of this chapter (see Fig. 5-2). In infants who have significant difficulty with ventilation or intubation, aside from oropharyngeal and nasal airways, an 0 silk suture can be placed at the base of the tongue to displace it anteriorly for assistance with ventilation or intubation.

Hemifacial microsomia is characterized by unilateral or asymmetrical development of the facial bones and muscles and frequently involves the ear. It manifests as hypoplasia of the malar-maxillary-mandibular region and usually involves the temporomandibular joint. The vertebral pathology can involve the cervical vertebrae and can significantly reduce the cervical range of motion. Other associated anomalies of hemifacial microsomia include cardiac defects (such as ventricular septal defect, tetralogy of Fallot, and coarctation), renal defects, and neurologic defects (such as hydrocephalus). Patients with hemifacial microsomia can have significant upper airway obstruction and OSA.

Airway management is a major concern in these patients. Mask ventilation may be difficult because of the facial asymmetry. Intubation is challenging because of the micrognathia and asymmetrical mandibular hypoplasia and potentially because of the decreased cervical range of motion. This difficulty may decrease with age but may increase after surgical reconstruction. Successful ventilation and intubation of infants has been reported using an LMA and fiberoptic laryngoscopy.¹³³

Anesthetic Management

The anesthetic management of infants with craniofacial anomalies begins with a complete preoperative evaluation. The history should define the anomaly and identify any associated syndromes. Infants and children with syndromes may have more complex airways, involvement of other organs, and more complicated surgical repair with more bleeding. Associated anomalies that can present a challenge to anesthesiologists include facial and airway features that make mask ventilation and intubation difficult. Airway pathology can also cause obstruction, and some of these children have OSA. A history of fatigue or sweating with feedings, cyanosis, and syncope are suggestive of an underlying cardiac anomaly. Cardiac abnormalities are associated with some syndromes, such as Treacher Collins syndrome, Apert syndrome, Pfeiffer syndrome, Carpenter syndrome, and hemifacial microsomia. In addition, some of these infants and children may have increased ICP that can manifest as headaches, vomiting, and somnolence, although chronically elevated ICP is often asymptomatic.

A thorough examination of the airway can be difficult in infants. Features that may predict difficulty with mask ventilation include midface hypoplasia and an enlarged tongue. In addition, a small mandibular space, decreased jaw opening and translocation, and decreased neck flexion and extension are predictive of difficult intubation. Additional examination should focus on identifying heart murmurs, and in infants with syndactyly, potential intravenous and arterial access sites. For reconstructions that involve significant blood loss, a preoperative hematocrit level should be obtained, and typing and crossmatch should be performed. Glucose levels should be monitored in formerly premature infants and infants younger than 2 months of age. Most children older than 1 year of age can be premedicated, but this is rarely necessary in those younger than 10 months old. Children with evidence of airway obstruction or increased ICP should be premedicated cautiously. Endocarditis prophylaxis should be considered for patients with congenital heart disease, per the American Heart Association guidelines.³⁸

Airway management in these patients can be very challenging. The difficulty may become evident during attempts at ventilation, intubation, or both. Fortunately, difficult airways are not common. However, the incidence is higher in patients with syndromes and in patients who have had previous reconstruction. Many techniques have been successfully described for infants and

children, and these include using a Bullard laryngoscope, LMA, air-Q LMA, flexible fiberoptic scope, and video laryngoscope.* A combination of techniques may be required to secure the airway. For example, an LMA has been used to facilitate passage of fiberoptic scopes and endotracheal tubes¹²⁴ (Fig. 5-3, A). An endotracheal tube/LMA size chart can be helpful for choosing the appropriate equipment to ensure success if an air-Q is not available. An air-Q LMA does not require an alteration of the endotracheal tube size. Both the tube and the pilot balloon can fit through the lumen of an air-Q LMA because of the removable cuff¹³⁵ (Table 5-9). The endotracheal tube can be secured while removing the LMA by telescoping a smaller endotracheal tube through the top of the larger endotracheal tube (Fig. 5-3, B). Commercial-grade “pushers” are available and are provided with the air-Q LMA. Cuffed endotracheal tubes may be more challenging to use with standard LMAs, because the balloon on the endotracheal tube may not fit through the lumen of the smaller LMAs. In this situation, uncuffed endotracheal tubes should be passed through an LMA of size 3 or smaller.

Preparation for Pediatric Procedures

Some infants with craniofacial anomalies require a tracheostomy because of significant upper airway obstruction.^{130,136} Adequate preparation involves having all of the necessary equipment available, with personnel trained and experienced in the use of these airway instruments. A pediatric otorhinolaryngologist may need to be immediately available.¹³²

Intraoperative Considerations

There are several intraoperative considerations for managing anesthetic for craniofacial repairs. Often these procedures are lengthy and expose infants to the risks of hypovolemia, hypothermia,

*References 58, 59, 65, 122, 129, 134.

Table 5-9 Laryngeal Mask Airway–Endotracheal Tube Compatibility

	LMA Size	Endotracheal Tube Size
Standard LMA	1.5	4.0 uncuffed
	2.0	4.5–5.0 uncuffed
	2.5	5.5 uncuffed
	3.0	6.0 uncuffed
	4.0	6.0 cuffed

	Weight (kg)	air-Q Size	Maximum Endotracheal Size (cuffed)
air-Q LMA	<7	1	4.5
	7–17	1.5	5.0
	17–30	2	5.5
	30–50	2.5	6.5
	50–70	3.5	7.5
	70–100	4.5	8.0

LMA, Laryngeal mask airway.

blood loss, and venous air emboli. Craniofacial procedures performed during an infant's first year of life include cranial vault remodeling, frontoorbital advancement, strip craniectomy (open and endoscopic), spring-mediated vault expansion, and distraction osteogenesis. Cranial-based procedures can involve significant blood loss because of the duration of the procedure and because of complications such as entering the sagittal sinus. Some studies suggest that 90% to 100% of these pediatric patients require blood transfusion.^{126,137} Endoscopic strip craniectomy, which is typically performed to correct sagittal synostosis, usually results in less blood loss.¹³⁸ Infants in particular are at risk for needing transfusions, because preoperatively they can be at the nadir of physiologic anemia (2 to 3 months of age), and the head contributes significantly more to the body surface area than in an older child or adult. Preparation for these procedures requires a baseline hematocrit level, blood type, and crossmatch. Adequate intravenous access must be obtained for resuscitation. In infants, at least two large-bore (18- and 22-gauge) peripheral intravenous catheters should provide adequate access. Arterial pressure monitoring is recommended for a beat-to-beat analysis of blood pressure and intravascular volume status and for blood gas monitoring. Some centers require central venous access for resuscitation and monitoring of central venous pressure.

Proposed techniques to minimize blood loss include surgical techniques and medical or pharmacologic techniques. Surgical techniques include scalp clips and needle-tip cautery. Medical techniques include preoperative autologous donation, acute normovolemic hemodilution, cell salvage, hypotension, antifibrinolytic therapy, and preoperative administration of recombinant erythropoietin (Epogen and Procrit). Most centers that perform cranial vault reconstructions did not use blood conservation techniques as of 2011.¹³⁹

Preoperative autologous donation and acute normovolemic hemodilution are techniques that have been described in older patients. No data currently support these techniques in infants

undergoing craniofacial surgery. The technique is limited in this population because of infants' small size, lower hemoglobin level, and reduced physiologic response to hemodilution, compared with that of adolescents.

Hypotensive anesthesia has been recommended for craniofacial surgery for decades, but it has not been well studied. A recent prospective study comparing two mean arterial blood pressures did not find a difference in the total amount of autologous blood given or the number of patients who were transfusion free.¹⁴⁰

In the past, the use of a Cell Saver system has been reported to be impractical for small pediatric patients because of the size of the collection reservoir. However, cell salvage reservoirs are now available in sizes as small as 25 ml. This technology may reduce the rate of autologous blood transfusions in infants undergoing craniofacial surgery. In a prospective observational study evaluating the use of a Cell Saver device with a 55 ml pediatric bowl for patients pretreated with erythropoietin, only 30% of the infants undergoing cranial vault remodeling required allogeneic blood, compared with 57% of historical controls.¹⁴¹

Antifibrinolytics have evolved significantly over the past decade. Aprotinin is no longer available because of the renal and myocardial complications associated with it in adults. Tranexamic acid and aminocaproic acid are alternatives that have filled the void. Two prospective blinded studies have demonstrated the efficacy of tranexamic acid. This antifibrinolytic reduces the volume of allogeneic blood exposure and increases the number of patients who are transfusion free.^{142,143} Although efficacy has been demonstrated, the safety of tranexamic acid is still being determined. Tranexamic acid has been associated with increased seizures after cardiac surgery¹⁴⁴; this seems to be dose dependent. In addition, this side effect has not yet been described after craniofacial surgery. The optimal dose of tranexamic acid has not been defined, but pharmacokinetic studies suggest that loading doses as low as 10 mg/kg with maintenance of 5 mg/kg/hr may be adequate to maintain a therapeutic plasma level.¹⁴⁵ The dose used in one of the efficacy trials was a 15 mg/kg loading dose, followed by 10 mg/kg/hr.

Preoperatively, recombinant erythropoietin decreases transfusion requirements for infants undergoing craniostomy repair. The reported dose of erythropoietin is 300 to 600 units/kg given subcutaneously once per week, along with oral iron supplementation. Erythropoietin is started 3 to 4 weeks before surgery. A prospective study of once-weekly dosing decreased the incidence of transfusion from 93% to 57% in infants undergoing craniostomy repair.¹⁴⁶

Prevention of Complications

Venous air embolism (VAE) is a potential complication of craniofacial and neurosurgical procedures. It can present with hemodynamic instability and result in death. VAE occurs commonly in pediatric patients having cranial-based procedures. A prospective study using precordial Doppler imaging in infants and children undergoing craniostomy repair detected VAE in 82% of patients. Hypotension secondary to VAE developed in 31%, but none developed cardiovascular collapse.¹⁴⁷ The incidence of VAE in this study was higher than the previously reported incidence of 66%.¹⁴⁸

Infants may be at increased risk for VAE, because significant hemorrhaging can occur during cranial vault remodeling, resulting in low central venous pressures. In addition, the relatively large size of an infant's head may raise the surgical site above the level of the heart, thereby increasing the pressure gradient for air entrainment. Some advocate placing central venous lines to monitor the trend of central venous pressures and minimize the risk of air embolism. However, to date there are no data to suggest that central venous pressure monitoring decreases the risk of VAE. Management of VAE begins with preventing hypovolemic states by providing adequate volume resuscitation and using precordial Doppler imaging for early detection of VAE. Lowering the

Fig. 5-4 Prone positioning for cranial vault remodeling. Plastic drapes from a Bair Hugger are applied. They act as a barrier to blood and irrigation. (Courtesy of Joseph Losee, MD.)

head of the bed, flooding the surgical field with saline solution, applying bone wax, discontinuing nitrous oxide, and providing inotropic support have been used for acute management of VAE.

Craniofacial procedures can be very lengthy, often lasting several hours. Complications resulting from long surgical procedures include skin breakdown, neuropathic injury, and hypothermia. Attention must be paid to the initial setup to ensure adequate positioning and padding to minimize these intraoperative injuries. Infants undergoing cranial vault remodeling may be placed in the prone position, with protection of the face and eyes.

Patients with syndromes that alter the architecture of the midface can present challenges when they are placed in the prone position, because it may be more difficult to adequately protect the face and eyes. An example of the initial setup is shown in Fig. 5-4. The infant is placed on a full-access forced-air warming system to minimize hypothermia, and the surgical site (the head) is isolated from the body with plastic drapes. This not only minimizes convective and radiant heat loss but also prevents conductive heat loss to a wet bed from irrigation and blood.

Postoperative Care

The postoperative management of infants undergoing craniofacial surgery depends on coexisting morbidities and the procedure performed. In patients who have had distractors placed, airway management may be more difficult after extubation because of the location of the device. Mask ventilation can be very difficult with external mandibular distractors in place. Airway equipment, including appropriately sized LMAs, should be available after extubation. External maxillary (midface) distractors are not typically placed in infants; however, their use in older children can make access to the airway more challenging; the presence of personnel and equipment in the operating room to remove part of the device is essential.¹⁴⁹

Infants having cranial vault remodeling and frontal orbital advancement can lose a significant amount of blood intraoperatively. If these patients are adequately resuscitated and hemodynamically stable, they can often be extubated in the operating room. Infants with difficult airways or significant airway obstruction and those who have had intraoperative complications may benefit from delayed extubation in the intensive care unit or operating room after their condition has stabilized.

Ongoing blood loss is common after major craniofacial surgery, and infants may require repeat transfusions in the immediate postoperative setting. Other complications that can occur

after craniofacial surgery include cerebral edema,¹⁵⁰ visual changes,¹⁵¹ cerebrospinal fluid leaks,¹⁵² infection,¹⁵² metabolic acidosis, and transfusion reactions.

Hyponatremia has been reported after major intracranial procedures and is common¹⁵³ but usually mild. It used to be attributed to syndrome of inappropriate diuretic hormone (SIADH). However, cerebral salt-wasting syndrome (CSW) may be the more likely cause. Both SIADH and CSW present with hyponatremia and high urine sodium levels. CSW is differentiated from SIADH by hypovolemia, high urine output, and low or normal antidiuretic hormone levels.¹⁴⁹ Proper diagnosis is important, because the management is different for the two syndromes. SIADH is treated with free water restriction, whereas CSW is managed with isotonic fluid replacement (normal saline solution) for maintenance and urine losses. Closely following the postoperative sodium levels will help guide therapy.

Patients With Epidermolysis Bullosa

Epidermolysis bullosa is a group of disorders of the stratified squamous epithelium that result in blistering, mucosal injury, and scarring after relatively minor mechanical forces.¹⁵⁴ The clinical effects range from minor disability with limited impact on functional capacity to death in the most severe cases. There are three major subtypes of epidermolysis bullosa: dystrophic epidermolysis bullosa, epidermolysis bullosa simplex, and junctional epidermolysis bullosa. They are defined by the dermal level in which blistering occurs. Patients with epidermolysis bullosa may undergo a variety of procedures that require the care of an anesthesiologist. Providing safe and effective anesthesia care for these patients can present significant challenges for the perioperative team.

The underlying pathology of epidermolysis bullosa affects many organ systems. Patients can develop blistering lesions of the mouth and oropharynx. The pain associated with these lesions can limit oral intake and result in nutritional deficiencies. Rarely, this results in dilated cardiomyopathy from selenium or carnitine deficiency.¹⁵⁵ A patient's poor nutritional status may also be reflected in abnormal electrolyte levels, compounded by ongoing fluid losses from blisters and denuded skin. Recurrent oral infections cause dental caries, oral scarring, and contractures that can limit mouth opening and may make intubation difficult. Scarring and contractures around the neck can also make intubation difficult by limiting neck mobility.¹⁵⁴

Recurrent injury to the esophagus leads to esophageal strictures, dysmotility, and gastroesophageal reflux. Recurrent episodes of streptococcal skin infections can lead to postinfectious glomerulonephritis with resulting renal dysfunction. The eyes can also be involved, and conjunctival bullae can develop with minimal mechanical stress. Anemia can occur in these patients.¹⁵⁶ The mechanism is unknown, but iron deficiency, poor nutritional intake, recurrent infections, and renal dysfunction may play a role. Treatment for epidermolysis bullosa may consist of topical and, rarely, oral steroids. Possible adverse effects of steroids include osteoporosis and adrenal suppression. Acute pain is common in infants and children with epidermolysis bullosa. Chronic pain ultimately develops in older patients, and this can result in chronic use of opioids.

Anesthetic Management

Common procedures performed for patients with epidermolysis bullosa include dental rehabilitation, esophageal dilation, Nissen fundoplication, skin biopsy and excision, and correction of pseudosyndactyly and contractures. Anesthetic management begins with the preoperative evaluation. The goal of the preoperative visit is to identify the severity of the disease and the nature of any coexisting diseases. Specifically, for patients with severe nutritional deficiencies, an echocardiogram and metabolic profile should be obtained to detect any underlying cardiac disease and/or electrolyte abnormalities. The degree and severity of gastroesophageal reflux needs to be

identified so that preparations can be made to minimize the risk of aspiration. For patients with a history of glomerulonephritis, blood urea nitrogen and creatinine levels should be checked to assess the degree of renal dysfunction. Anemia is common, and a preoperative hematocrit level should be obtained in most patients. Blood typing and crossmatching can be reserved for those who might require an intraoperative transfusion. Children who are chronically exposed to topical corticosteroids can have adrenal suppression and may require replacement steroids (2 mg/kg of hydrocortisone). Exogenous steroids given to replace the normal increase in cortisol requirements are referred to as *stress-dose steroids*.

Physical examination should identify patients with potentially difficult airways. For example, those with significant mouth contractures that limit mouth opening may be very difficult to intubate with laryngoscopy. The examination should also identify areas of skin that are particularly vulnerable or that have recently been injured. These should be documented and particular attention paid to positioning and protecting these areas.

Premedication can be beneficial in children with epidermolysis bullosa. Midazolam given either orally or through a gastric tube is very effective for reducing preoperative anxiety and may reduce the risk of injury to the skin during induction of anesthesia by facilitating patient cooperation. Intramuscular injections should be avoided. If an intravenous catheter is available, an H₂ receptor blocker (ranitidine [Zantac], 1 mg/kg) and metoclopramide (0.1 to 0.2 mg/kg) can be given to patients with gastroesophageal reflux disease. Adolescents with gastroesophageal reflux disease can also be given a nonparticulate antacid (Bicitra, 15 ml) orally or by gastric tube.

Transfer and Monitoring

Every effort should be made to minimize the patient's exposure to shear forces during table-to-table transfers. Lifting the patient on a flat, crease-free sheet and padding the surface of the bed and the patient's ankles with egg crate foam padding will help to protect against injury to the skin. Patients should never be transferred or repositioned by sliding. This shear force can cause significant injury.

Monitors can pose a challenge for patients with epidermolysis bullosa, because most monitors have adhesive coatings. ECG leads can be placed on the skin on the back after their adhesive coating has been removed. A cut-out square from a defibrillator pad can provide a nonadhesive barrier and will conduct an electrical signal.¹⁵⁷ Lubricated gauze such as Vaseline gauze can be placed on top of the leads to keep them in place. A pulse oximeter should also be secured over a finger after the adhesive backing has been removed. A clip pulse oximeter probe may be ideal and can be placed on the finger or earlobe. Likewise, temperature probes that are well lubricated can be placed in the esophagus. Noninvasive blood pressure cuffs may pose more of a challenge. For minor, short procedures, some suggest not using them. An arterial catheter can be used in place of a sphygmomanometer. Others have described the safe use of noninvasive blood pressure cuffs when they are placed on extremities that have been well padded with wool or polyvinyl chloride padding.^{154,157}

Induction

Induction of anesthesia can be achieved using an inhalation or intravenous technique. An intravenous catheter can be safely placed, but a tourniquet should not be used. Gentle circumferential pressure using a hand covered with a lubricated glove provides adequate venous engorgement. EMLA cream has been successfully used in children with epidermolysis bullosa.¹⁵⁸ A catheter can be secured with a nonadhesive dressing such as Vaseline gauze and a soft padded wrap (Fig. 5-5). The mask should be covered with a lubricant such as petroleum jelly or lubricated gauze (paraffin gauze). Induction should be calm and free from struggle. All airway equipment

Fig. 5-5 Intravenous placement and protection are facilitated by the application of a soft cotton wrap. A pulse oximeter is applied without the use of adhesive backing. (Courtesy of Larry Borland, MD. Permission granted by family for photography.)

Fig. 5-6 Nasal intubation in a patient with epidermolysis bullosa. The tube is secured with lubricated gel foam. (Courtesy of Larry Borland, MD. Permission granted by family for photography.)

(laryngoscope, oral and nasal airways, and endotracheal tubes) should be well lubricated. If possible, the endotracheal tube should be one-half size smaller than typically would be used.

A fiberoptic scope may be necessary to successfully intubate some patients with epidermolysis bullosa. Generally, oral intubation is recommended, but nasal intubation can be safely performed with well-lubricated and appropriately sized nasal tubes (Fig. 5-6). The endotracheal tube can be secured with an external “arm” that is attached to the bed or with lubricated gauze that is gently wrapped around the patient’s head. Oral and pharyngeal lesions have occurred after intubation, but the incidence is not high if appropriate measures are taken.¹⁵⁹ The use of an LMA has been described in patients with epidermolysis bullosa. Ames et al¹⁵⁷ reported the use of the LMA on 57 occasions, with only one case of a new lingual bulla.

Postoperative Care

Postoperative pain management for patients with epidermolysis bullosa may be difficult because of the combination of acute and chronic pain. Opioids can be given intravenously in the form of

Fig. 5-7 Proportion of TBSA in relation to age (Rule of Nines). The contribution of the head to the body surface area is larger in infants and children.

patient-controlled analgesia. Regional analgesia has been successful for postoperative pain control, and peripheral nerve blocks such as brachial plexus, axillary, and ankle blocks have also been described.¹⁶⁰⁻¹⁶² Placing peripheral nerve blocks is complicated by the poor integrity of the skin.

The skin preparation should be sprayed or poured on without any wiping. No adhesive drapes can be applied, and some investigators have advocated not using nerve stimulators, because the positive electrode is applied with an adhesive patch. Alternatively, a percutaneous needle may be used. The catheter can be secured to the skin with sutures. Neuraxial blocks with caudal, epidural, and intrathecal anesthesia have also been described.^{163,164}

Patients With Burn Injury

Burns occur in approximately 1.3 million children every year, and 3000 children die each year from them, making burns the second leading cause of traumatic death in childhood.¹⁶⁵ The most common cause of burns in this age group is hot liquid scalds. Other causes include flame or thermal heat, electricity, and chemical and radiation exposure.

The depth and the percentage of body surface area involved define the severity of the burn. The components of body surface area in pediatric patients are different from those in adults. The head contributes more to the body surface area in infants and children, and the extremities contribute less¹⁶⁶ (Fig. 5-7).

The injuries from burns can affect almost every organ system. The skin is the primary barrier against dehydration, fluid and electrolyte loss, and bacterial infection. Burns destroy this barrier and expose the body to these risks. The initial insult to the skin results in an inflammatory response and causes tissue edema. Cytokines, arachidonic acid metabolites, and oxygen free radicals mediate the edema. Fluid loss from the intravascular space to the surrounding tissue can be significant, and edema may develop at sites remote from the burn. This edema fluid is rich in albumin and in a moderate to large burn can account for profound albumin loss over the course of a few days.¹⁶⁷

The initial cardiovascular response to a burn is decreased cardiac output. The decrease occurs because of a reduction in preload (intravascular volume loss) and an increase in systemic vascular resistance and PVR.¹⁶⁸ Direct myocardial depression results from circulating factors such as tumor necrosis factor, vasopressin, and oxygen free radicals. The decrease in cardiac output is quickly replaced in hours to days by an increase in cardiac output (two to three times the baseline) after the burn. After the initial injury, a hypermetabolic state develops that lasts until the wounds are closed. This state is a neuroendocrine response fueled by an increase in catecholamines, glucocorticoids, glucagon, and cytokines. Aside from an increase in cardiac output, hypertension is common.

Lung injury from burns is a significant cause of morbidity and mortality and can occur in the upper or lower airway. Heat exposure to the larynx can cause edema and obstruction. Increased capillary permeability can occur at sites remote from the burn and may contribute to upper and lower airway edema. Any evidence of a burn to the head or neck or evidence of soot on the face should raise suspicion of an airway injury. Interventions to secure the airway should not be delayed, especially in patients with coughing, wheezing, or stridor. This is more critical in pediatric patients, because small changes in the radius of their airways will cause a significantly greater increase in airway resistance.¹¹ (Resistance is inversely proportional to the fourth power of the airway radius.)

Inhalation injuries can result from exposure to carbon monoxide and hydrogen cyanide. Smoke inhalation during fires, especially in closed spaces, increases this risk. Carbon monoxide avidly binds hemoglobin (200 times greater than oxygen) and decreases the ability of hemoglobin to deliver oxygen to the tissues, resulting in asphyxiation. The half-life of carbon monoxide is reduced from 4 hours to 40 minutes by exposing the patient to high concentrations of oxygen.^{165,169} Carboxyhemoglobin levels should be measured in all patients being treated for burns that occurred in a house fire or a fire in a closed space. These patients should be treated with high-concentration ($\text{FiO}_2 = 1$) oxygen. Cyanide poisoning should be suspected with all inhalation injuries. Treatment consists of sodium thiosulfate and sodium nitrite, although care must be taken with sodium nitrite, because it can cause hypotension.^{170,171}

Anemia of thermal injury is common after burns. Its cause is multifactorial and includes hemorrhage, hemolysis, and decreased erythroid production.^{172,173} The initial loss of red cells occurs as a result of bleeding and hemolysis. The surviving erythrocytes have a decreased half-life that appears to be related to a circulating inhibitor, which explains the reduced half-life of transfused blood as well. Erythrocyte production is also decreased. Erythropoiesis is diminished because of an inhibitor of erythroid stem cells, which can result in profound anemia.¹⁷²

The physiologic changes that occur after burns affect the pharmacokinetics and pharmacodynamics of many drugs. Pharmacokinetic changes include alterations in distribution and clearance. The tissue edema that occurs after burns increases total body water and increases the volume of distribution. Larger doses of intravenous medications may be required to achieve adequate plasma levels. A hypermetabolic state results in hepatic enzyme induction and may enhance drug clearance. Protein binding is altered as well. Albumin levels decrease significantly after burns because of intravascular losses to surrounding tissue. Conversely, alpha-1-acid glycoprotein is an acute-phase reactant and increases after burns. Drugs that bind to these proteins (for example, acidic and neutral drugs, which bind with albumin, and basic drugs such as bupivacaine, fentanyl, and alfentanil, which bind with alpha-1-acid glycoprotein) have altered free drug plasma levels.

Clinical Management

Thermal injuries in adults and children result in a decreased sensitivity to nondepolarizing neuromuscular blockers and an increased sensitivity to depolarizing neuromuscular blockers.¹⁷⁴ Larger doses of nondepolarizing neuromuscular blockers are required to achieve adequate clinical results

because of the increased extrajunctional acetylcholine receptors.^{175,176} The duration of neuromuscular blockade with nondepolarizing blockers is also diminished. Larger doses of nondepolarizing neuromuscular blockers shorten the onset time and prolong the duration of neuromuscular blockade but do not achieve the onset time and duration seen in nonburned patients.¹⁷⁷ Depolarizing neuromuscular blockers such as succinylcholine (Anectine and Quelicin) should not be used, because the increased number of acetylcholine receptors may cause hyperkalemia. It is not known how soon after a burn this sensitivity begins, but succinylcholine should probably not be used 24 hours after a burn has occurred. This effect can persist for years after a burn.

Surgical Management

Surgical management of burn patients depends on the depth of the burn. Superficial burns can be managed with dressing changes. Partial-thickness burns may require skin grafting if they do not heal after 2 to 3 weeks of dressing changes. Full-thickness burns require skin grafting. Surgical debridement of burned tissue can result in significant bleeding. There are several descriptions of extensive or massive hemorrhage during surgical debridement.¹⁷⁸ Pediatric patients have smaller blood volumes and a larger surface area/weight ratio and are at particular risk of significant blood loss. Many methods have attempted to minimize blood loss, including subcutaneous and topical vasoconstrictors, tourniquets, normovolemic hemodilution, and induced hypotension.¹⁷⁹ Despite these techniques, significant bleeding can persist. A study using a dermabrader for surgical debridement of partial-thickness burns and needlepoint electrocautery for full-thickness burns resulted in significantly less bleeding. Some patients did not require transfusions.¹⁸⁰ In this study the donor sites were also infiltrated with saline solution and epinephrine. Doses of epinephrine of up to 10 µg/kg were used without adverse effects such as arrhythmias. In pediatric burn patients, doses greater than 10 µg/kg of subcutaneous epinephrine have been well tolerated.^{181,182}

Anesthetic Management

Anesthetic management of all burn patients begins with the airway. Evidence of inhalation injuries should prompt early intubation before airway edema occurs. Cuffed endotracheal tubes can be used safely in pediatric patients of all ages and should be considered in these patients, because high peak airway pressures may be required to successfully ventilate them. All patients with inhalation injuries need to be evaluated for carbon monoxide and hydrogen cyanide poisoning and should be treated with high-concentration oxygen.

Immediately after a burn, a patient can develop profound hypovolemia caused by hemorrhage and intravascular volume loss to surrounding tissue. The Parkland formula and Brooke formula help to guide the initial fluid resuscitation for the first 24 hours¹⁸³ (Box 5-1).

Box 5-1 Modified Parkland and Brooke Formulas for Pediatric Burn Reconstruction

Parkland Formula

$[4 \text{ ml/kg crystalloid} \times \% \text{ TBSA burned} \times \text{Weight (kg)}]^* + \text{Maintenance fluids}^\dagger$

Brooke Formula (modified)

$[0.5 \text{ ml/kg crystalloid} + 1.5 \text{ ml/kg colloid} \times \% \text{ TBSA burned} \times \text{Weight (kg)}]^* + \text{Maintenance fluids}^\dagger$

*Administer the first half of the volume over 8 hours and the second half over 16 hours.

†Maintenance fluids = 4 ml/kg/hr for the first 10 kg + 2 ml/kg/hr for the second 10 kg + 1 ml/kg/hr for every kg over 20 kg. TBSA, Total burned surface area.

However, these estimates are not completely accurate for managing infants and children. Children have a higher surface area/weight ratio. Formulas that base resuscitation on percentage of surface area burned and weight may underestimate the fluid requirements in children. In children younger than 4 years of age, calculating the fluid requirements from the previously mentioned formulas and then adding their daily maintenance requirements has been suggested.¹⁸⁴ Fluid losses in burned pediatric patients may be profound, exceeding 4000 ml/m² of burned skin, compared with 2500 ml/m² in adults.^{183,185}

During surgical debridement of full-thickness and partial-thickness burns, patients can have massive blood loss and fluid shifts. Surgical techniques, as described earlier in the chapter, can minimize bleeding. Regardless, the need for transfusions is very common, and adequate vascular access and monitoring are essential before surgery. This may include placing arterial and central venous catheters. Frequent blood gas analysis should be performed to assess the adequacy of resuscitation and ventilation. Many burned patients can have low ionized calcium levels that persist for weeks.¹⁸⁶ Ionized calcium should be measured and replaced, especially during resuscitation with citrated blood products.

Burn patients become poikilothermic because of the significant evaporative heat loss that occurs from open wounds. This is especially true in pediatric patients, because their body surface area is relatively larger. Every effort must be made to minimize heat loss when these patients come to the operating room. Steps to decrease heat loss include raising the operating room temperature as high as tolerated by the operating room staff, radiant warming lights, forced warm air devices, and giving warm intravenous fluids. Wrapping the extremities and head in plastic may significantly decrease heat loss.

Adequate pain management is critical for pediatric burn patients. They have pain not only from the burn but also from therapeutic maneuvers such as repositioning, dressing changes, and surgical procedures. Opioids are the mainstay of pain management for burns. Most opioids have been prescribed for managing burns, including morphine, methadone (Dolophine and Methadose), and remifentanyl (Ultiva); however, morphine is the most common. The pharmacokinetics of opioids in burn patients is inconsistent, and few data are available for children. In three adult studies, the pharmacokinetics of morphine did not differ significantly from that of nonburned patients.^{187,188} However, Furman et al¹⁸⁹ found the volume of distribution and clearance to be smaller in burned patients, and the elimination of morphine was prolonged, compared with elimination in nonburned adults. Opioids can be delivered as a continuous infusion or through patient-controlled analgesia. Children older than 5 years of age start to understand the concept of patient-controlled analgesia. By 7 years of age, most children can use patient-controlled analgesia effectively. Other modalities have been used for breakthrough pain caused by dressing changes and surgical debridement. Ketamine is a very effective analgesic, and its safety profile is excellent. The hallucinations associated with its use can be very disturbing for children, but these can be reduced by giving a benzodiazepine such as midazolam. Ketamine may have the added advantage of reducing opioid tolerance and opioid hyperalgesia.

Regional anesthesia has been described for children with burns. Both neuraxial and peripheral nerve blockade have been reported and can provide very effective analgesia.^{190,191} The potential advantages are excellent analgesia and reduced exposure to systemic opioids. The disadvantage is that the location and extent of the burn may preclude placing a regional catheter. For appropriate cases, this technique should be considered.

KEY POINTS

General

- General anesthesia for infants and children is very safe.
- The concerns regarding the neurocognitive effects of anesthesia/sedation on the developing brain are not clearly defined.
- Recent prospective evidence did not identify any negative neurocognitive effect of general anesthesia on the developing brain.

Pediatric Physiology

- A neonate's heart (and to some degree an infant's heart) has a limited ability to increase stroke volume; neonates are poorly tolerant of bradycardia. Moreover, significant volume loads may more easily cause ventricular overload and failure.
- Pediatric patients are more prone to hypoxia because of (1) the larger closing capacity (the sum of the closing volume and the residual volume; *closing volume* is the volume above the residual volume at which airway closure/collapse occurs in dependent lung zones), (2) more chest wall compliance, and (3) higher oxygen consumption.
- Neonates and infants are at increased risk of thermoregulatory instability, because they are at a higher risk of heat loss, and they have a decreased ability to produce heat.

Preoperative Evaluation

- Many craniofacial anomalies warrant concerns regarding difficult airways, OSA, and congenital heart disease, and these patients should be seen preoperatively by the anesthesiology team.
- Infants with a PCA of less than 45 to 50 weeks are at risk for apnea after general anesthesia and need to be observed overnight with an apnea/bradycardia monitor.
- Patients with OSA and sleep-disordered breathing can have disordered breathing and opioid sensitivity while recovering from the sedative effects of anesthesia. They may be poor candidates for same-day surgery.
- Children who have upper respiratory infections with fevers above 38° C (100.4° F), changes in behavior, purulent nasal drainage or cough, or wheezing during lung auscultation may benefit from having their surgeries postponed for 2 to 6 weeks.

Continued

KEY POINTS (continued)

Preoperative Evaluation—cont'd

- Separation from the family and introduction of a face mask can cause tremendous anxiety in children and may contribute to postoperative behavioral changes such as bed-wetting, increased separation anxiety, and nightmares. Anxiety can be reduced by giving midazolam 0.5 to 1 mg/kg, which should be used with caution in patients with severe upper airway obstruction or increased ICP.

Anesthetic Management

- Induction of anesthesia in a pediatric patient can be achieved using an inhalation or intravenous technique.
- Equipment that can be used to secure the airway in anesthetized children includes but is not limited to a mask, LMA (air-Q), an endotracheal tube, a laryngoscope, a flexible fiberoptic scope, and a video laryngoscope.
- Sedation from recent anesthetic and pain medications given in the recovery room can cause hypoventilation and airway obstruction. Airway obstruction from swelling of the airway and the soft tissues surrounding it may occur either in the operating room or in the recovery room.
- PONV is the most common immediate cause of postoperative anesthetic morbidity in children.
- Children may develop emergence delirium postoperatively, characterized by confusion, inconsolability, psychomotor excitement, and dysphoria.
- Epidural and peripheral nerve blocks have been described, and the benefit may be improved analgesia, decreased duration of hospitalization, and increased tissue oxygenation.

Craniofacial Surgery

- Craniofacial anomalies are classified as follows: (1) clefts, (2) synostosis, (3) hypoplasia, (4) hyperplasia, and (5) unclassified.
- Treacher Collins syndrome is an example of a craniofacial cleft and may present with a difficult or impossible airway, upper airway obstruction, and congenital heart disease.
- Anesthetic concerns during craniofacial surgery include potentially difficult airways (ventilation and intubation), significant blood loss, venous air emboli, and hypothermia.
- Techniques described to minimize blood use include needlepoint electrocautery, scalp clips antifibrinolytic therapy, cell salvage, and synthetic erythropoietin.

- Postoperative concerns after craniofacial surgeries (cranial vault reconstructions) include ongoing blood loss, metabolic acidosis, transfusion reactions, and hyponatremia.

Epidermolysis Bullosa

- The underlying pathology of epidermolysis bullosa affects many organ systems and may cause cardiac dysfunction, renal failure, reflux, malnutrition, anemia, and chronic pain.
- Children who are chronically exposed to topical corticosteroids can have adrenal suppression and may require stress-dose steroids.
- Patients should not be transferred or repositioned by sliding. Lifting patients on a flat, crease-free sheet and padding the surface of the bed and ankles with egg crate foam padding will help to protect against injury to the skin.
- Monitors can pose a challenge for patients with epidermolysis bullosa. The following measures can help to prevent complications:
 - ECG leads can be placed on the skin or on the back after their adhesive coating has been removed.
 - The pulse oximeter should be secured over a finger after the adhesive backing has been removed.
 - Temperature probes that are well lubricated can be placed in the esophagus.
 - Blood pressure cuffs are safe when placed on extremities that have been well padded with wool or PVC padding.
- All surfaces that come in contact with the skin need to be well lubricated to minimize shear forces (including masks, gloves, laryngoscopes, LMAs, and endotracheal tubes).
- Airway management can be challenging in patients with epidermolysis bullosa because of limited mouth opening and neck mobility.

Burn Surgery

- The injury caused by burns can affect almost every organ system.
- Edema can develop at sites remote from the burn.
- The initial cardiovascular response to a burn is decreased cardiac output. This is quickly replaced by an increase in cardiac output (two to three times the baseline) hours to days after the burn and lasts until the wounds are closed.

Continued

KEY POINTS (continued)

Burn Surgery—cont'd

- Any evidence of a burn to the head or neck or evidence of soot on the face should raise suspicion of an underlying airway injury. Interventions to secure the airway should not be delayed, especially in patients with evidence of coughing, wheezing, or stridor.
- Inhalation injuries can result from exposure to carbon monoxide and hydrogen cyanide.
- Anemia of thermal injury is common after burns.
- The hypermetabolic state results in hepatic enzyme induction and may result in enhanced drug clearance. Protein binding is altered, because albumin decreases and alpha-1 acid glycoprotein increases after burns.
- Larger doses of nondepolarizing neuromuscular blockers are required to achieve adequate clinical results because of the increased extrajunctional acetylcholine receptors.
- Depolarizing neuromuscular blockers such as succinylcholine should not be used for 24 hours after a burn, because the increased number of acetylcholine receptors may cause hyperkalemia.
- Surgical debridement of burned tissue in children can cause significant bleeding leading to massive hemorrhage.
- A technique for surgical debridement using a dermabrader for partial-thickness burns and needlepoint electrocautery for full-thickness burns may result in significantly less bleeding.
- Burn patients are poikilothermic because of the significant evaporative heat loss from open wounds.
- Adequate pain management is critical for pediatric burn patients and may consist of opioids, ketamine, and regional anesthesia.

Closing volume is the volume above residual volume at which small airway closure (atelectasis) begins to occur in dependent lung regions. This study demonstrated that children have high closing volumes. The closing volume of a 7-year-old child was similar to that of a 45-year-old adult, and "airway closure" was present during normal tidal volume breathing. This airway closure resulted in shunting and oxygen desaturation.

Apnea after general anesthesia is a concern in formerly premature infants. This study evaluated the incidence of postoperative apnea, oxygen desaturation, and bradycardia in 18 formerly premature infants (less than 51 weeks' PCA) undergoing inguinal herniorrhaphy under spinal versus general anesthesia. They found that although there was no difference in the incidence of apnea between the two groups, the infants who received general anesthesia had lower postoperative oxygen saturation and more significant bradycardia. Several studies in this area have been the impetus for pediatric anesthesiologists to keep formerly premature infants for overnight observation with an apnea-bradycardia monitor after general or regional anesthesia.

This study highlights the fact that children with obstructive sleep apnea (OSA) may have lower opioid requirements than children without OSA. The children in this study who had the lowest preoperative overnight oxygen saturation values required the lowest amount of opioids after tonsillectomy. The findings suggest that the dose of opioids for children with OSA should be reduced to minimize the risk of respiratory complications.

Children who are very anxious before and during the induction of anesthesia are at increased risk of developing postoperative behavioral changes. These changes include increased separation anxiety, sleep disturbances, eating disturbances, and oppositional-defiant behavior. The risk of postoperative behavioral changes is reduced with the preoperative administration of midazolam.

Pediatric and Fetal Wound Healing

Jacqueline S. Israel • Timothy W. King

he process of normal cutaneous wound healing in infants, children, and adolescents is very similar to that of adults. It is a highly complex process, and when it is affected by various local and systemic factors, healing may go awry. In contrast to postnatal wound healing, fetal healing is a distinct, unique process that investigators are beginning to understand. This chapter outlines cutaneous wound healing in pediatric patients, offers examples of factors that contribute to abnormal healing, introduces what is currently known about fetal wound healing, and provides an initial approach to wound care in infants and children.

WOUNDS IN INFANTS AND CHILDREN

A wound results from damage to normal tissue. The mechanism of damage may vary; in the infant and pediatric populations, wounds are often acute. Plastic surgeons may encounter many types of wounds in an infant, child, or adolescent, as described in Table 6-1.¹⁻³

Once a wound has been created, *wound healing* is a complex series of events that lead to repair. *Cutaneous wound healing* consists of a coordinated, complex series of events that can be thought of as a “temporal and spatial” process.⁴ The temporal component begins at the time of injury and continues for months to years as the scar matures. Healing can also be conceptualized spatially, occurring simultaneously on molecular, cellular, tissue, organ, and system levels.⁴

Table 6-1 Examples of Wound Types

Wound	Description
Abrasion	Frequently involves only the epidermis; often heals by secondary intention
Bite	Should have a high index of suspicion for infection (for example, polymicrobial, rabies, tetanus)
Chemical burn	Can occur from povidone-iodine, alcohol-based washes, adhesive removers
Crush	Difficult to assess wound severity; monitor for signs of compartment syndrome
Extravasation	Common in neonates and infants; caused by infusions (for example, crystalloids, electrolytes, chemotherapy)
Laceration	Ideally closed within 8 hours, or up to 24 hours if the face is involved
Maceration or “moisture-associated skin damage”	As seen with diaper dermatitis; can lead to hypergranulation, infection ³
Pressure ulcer	Should have a high index of suspicion in hospitalized infants and children; frequent position changes are paramount
Puncture	Should have a high index of suspicion for a foreign body; often heals by secondary intention
Sting	May result in systemic effects requiring epinephrine, steroids, or antihistamines
Surgical incision or wound	Often a clean wound that can be closed primarily
Tear/blister	More common in pediatric patients (thin skin); often iatrogenic
Thermal burn	Can be caused by hot water, light therapy, metal objects (electrodes, household items), fire; infants and children have different body surface area proportions compared with adults

NORMAL CUTANEOUS WOUND HEALING IN INFANTS AND CHILDREN

One should have at least a basic knowledge of normal healing to understand and approach clinical wound healing challenges. Normal wound healing is characterized by four discrete but overlapping stages: coagulation, inflammation, proliferation, and maturation (Fig. 6-1).

Coagulation

The process of *coagulation* begins with tissue injury, and hemostasis is the primary goal (Fig. 6-2). Platelets aggregate and form a fibrin plug (clot) through alpha-degranulation and the release of adhesive proteins, such as fibrinogen, fibronectin, thrombospondin, and von Willebrand factor.^{5,6} This clot acts as an initial matrix on which wound healing will occur. There is activation of both the intrinsic and extrinsic clotting cascades, which facilitates hemostasis and converts fibrinogen into fibrin, turning the clot into a gel-like matrix to facilitate cell migration. Platelets also release platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF-beta), which chemoattract inflammatory cells such as neutrophils and monocytes. After hemostasis has been achieved, local blood vessels vasodilate, promoting the influx of inflammatory cells. Activation of the complement cascade (C3a and C5a anaphylatoxins) increases blood vessel permeability, which also recruits inflammatory cells to the wound bed.⁶

Fig. 6-1 Stages of normal cutaneous wound healing.

Fig. 6-2 The process of coagulation.

Fig. 6-3 Inflammation.

Inflammation

The next step in the wound healing process is *inflammation*, which is characterized by a flood of inflammatory cells into the wound. The primary goal of this process is to rid the wound of bacteria, debris, and devitalized tissue (Fig. 6-3). The first to enter, within 24 to 48 hours after injury, are the polymorphonuclear leukocytes, or neutrophils.⁶ Neutrophils are recruited to the wound by TGF-beta1, PDGF, tumor necrosis factor alpha, and interleukin-1. Neutrophils exhibit oxidative burst, an oxygen-dependent process that kills bacteria through free radicals. They also cause phagocytosis of debris and release collagenases to degrade and remodel the wound matrix. When the wound becomes clean, neutrophils exit the wound bed. This is important, because if bacteria and debris persist, the neutrophils remain and may cause damage to nearby healthy tissue.⁶ Recent studies suggest that neutrophils are not essential for wound healing.⁷ This is in contrast to the role of the next cell to enter the wound, the monocyte; wounds will not heal properly if they are not present.⁷

Monocytes are the predominant cell type in the wound by 48 to 72 hours after injury.^{5,6} They are recruited to the wound by monocyte chemoattractant protein-1. On arrival, monocytes become activated and transform into macrophages. Macrophages scavenge the wound for foreign material, bacteria, and debris and release additional growth factors that activate endothelial cells, fibroblasts, and keratinocytes. They also participate in tissue degradation by secreting collagenases (matrix metalloproteinase [MMP]-1, MMP-9, and MMP-3).⁸ Lymphocytes are the final cells to enter during the inflammatory stage, appearing around 5 to 7 days after tissue injury. Their role is less clear.

Fig. 6-4 Proliferation.

Proliferation/Matrix Deposition

As inflammation declines, the process of *proliferation* begins, typically around day 4, and continues for up to 3 weeks. It is named for the migration of fibroblasts and generation of new tissue at the wound bed. During this phase, there is angiogenesis, collagen deposition, formation of granulation tissue, epithelialization, and wound contraction (Fig. 6-4).

Fibroblasts predominate beginning about days 3 to 5.⁶ Infants and children have been found to have higher numbers of fibroblasts during this phase, perhaps explaining the faster rate of wound healing often observed in this population.² Initially, there is a period of *fibroplasia*, whereby fibroblasts are brought to the wound by PDGF and TGF-beta. After migration to the wound, they begin to secrete extracellular matrix (ECM) components, such as loosely organized collagen and hyaluronic acid (HA). The adhesion proteins fibronectin, laminin, and tenascin are essential for fibroblast migration and attachment.⁶ Eventually, the platelet-fibrin clot (established during the coagulation phase) is replaced by a scaffold of fibronectin and HA, which is the basis for new tissue formation.

Collagen synthesis occurs on fibroblast ribosomes. Chains of collagen are assembled, and hydroxylation of specific prolines and lysines occurs. Ascorbic acid (vitamin C) is required for the enzyme prolyl hydroxylase to convert proline to hydroxyproline. After the individual collagen fibrils are synthesized, the enzyme lysyl oxidase organizes collagen molecules into collagen fibrils through covalent cross-linking.⁶ Both type I and type III collagen are synthesized. Collagen has many isoforms with subtle differences in molecular structure. These differences are responsible for the vast differences in the structures and functions of particular collagen molecules. For

example, bone is primarily type I collagen, whereas skin is approximately 80% type I and 20% type III collagen. Normal blood vessels are 80% type III and 20% type I collagen.

Another process during the proliferation phase is wound *contraction*. Open wounds decrease in size by contracting, minimizing the need for new tissue. Around week 2, some of the collagen-synthesizing fibroblasts transform into *myofibroblasts*, which facilitate narrowing of the wound by contracting along the edges of tension. *Neovascularization* also occurs. Fibroblast growth factor (FGF)-2 from macrophages stimulates endothelial cells to release tissue plasminogen activator and procollagenase, which digest the ECM and allow immature tubes of endothelial cells to grow into the wound. Vascular endothelial growth factor stimulates endothelial cell proliferation, and TGF-beta facilitates the differentiation of the vascular endothelial cell type. Alongside the process of angiogenesis, *granulation tissue* is formed. This process is primarily stimulated by PDGF and vascular endothelial growth factor. Granulation tissue is characterized by a dense bed of capillaries, fibroblasts, and immature ECM, and it seems to form more quickly in neonates and children than in adults.²

Reepithelialization of the wound begins as early as 24 to 48 hours after injury but is an important part of the proliferation phase.^{1,6} Keratinocytes at the wound edges become migrating keratinocytes and contain integrin receptors and actin filaments to facilitate migration and recreate a cellular barrier overlying the immature and evolving wound matrix (which contains collagen, fibrin, fibronectin, tenascin, and vitronectin).^{5,6,9} Both keratinocytes and fibroblasts secrete laminin and collagen IV, facilitating the progressive construction of a new basement membrane.⁶ Many growth factors and cytokines are involved in reepithelialization, including hepatocyte growth factor, FGF-7 and FGF-10, and transforming growth factor-alpha.⁵

Maturation

Wound remodeling, or *maturation*, occurs over weeks to months after injury. In this stage, inflammatory cells regress, and the scar becomes less pink and raised (Fig. 6-5). Tensile strength ultimately reaches approximately 70% to 80% that of normal, uninjured skin.⁹ By 3 to 5 weeks after the injury, fibroblasts are at the center of the wound and synthesize primarily type I and type III collagen. The process of collagen deposition and degradation (via MMP-1 and MMP-3) occurs concurrently for up to 1 year, and collagen becomes more densely packed as time progresses. FGF-1 and FGF-2 facilitate remodeling as the wound matures.

Compared with scars in adults, scars in children remain pink and elevated for a longer time. In addition, scars formed during the first 6 months of life become almost imperceptible, in contrast with scarring in older children. The reasons for this are not clear. This phenomenon may be related to two factors: (1) During the third trimester of fetal healing, scars become virtually absent, perhaps as a holdover from some of the phenomena from this period, and (2) in the transition from fetal to infant healing, there is a change in the predominance of collagen types (type III to type I). The unique aspects of fetal healing are discussed in more detail later in the chapter.

Fig. 6-5 Wound maturation.

ABNORMAL CUTANEOUS WOUND HEALING IN CHILDREN

Aberrant wound healing can result from both local and systemic factors.¹ In response to these factors, wound healing in any organ system reflects a balance between tissue regeneration and scar formation.⁹ In the case of pediatric cutaneous wound healing, scar formation predominates, and the formation of an organized scar is a normal biologic response to tissue injury.

As discussed by Gurtner and Wong,⁹ wound healing failure can be attributable to (1) inadequate regeneration of previously normal tissue (as seen with injuries to the central nervous system), (2) inadequate scar formation (as often seen in chronic wounds, such as those in patients with pressure ulcers and persistent inflammatory states), (3) excessive regeneration (as in the case of a neuroma), or (4) excessive scar formation (as in a hypertrophic scar or keloid). Any wound in a pediatric patient can be analyzed within the context of the local and systemic factors that affect the balance between regeneration and scar formation.

Issues Related to Aberrant Wound Healing

Fluid Collections and Edema

Edema can delay and preclude wound healing, particularly after the acute inflammatory response.² Excess fluid in and near a wound can present as a seroma or hematoma, which may result in ischemia or infection. Just as in adults, edema in children can be addressed with elevation, compression, and negative pressure wound therapy (NPWT) when appropriate.¹

Pressure

Mechanical pressure impairs normal wound healing mechanisms through local shearing forces and decreased blood flow. Compared with adults, infants and children have thin skin and are susceptible to pressure ulcers both in dependent areas and in tissue that is in contact with medical devices.³

Ischemia

Decreased oxygen delivery to tissues from ischemia is detrimental to wound healing.¹ Oxygen is required for aerobic metabolism, macrophage oxidative burst, fibroblast proliferation, and collagen production. In children, this is often most relevant in the setting of hypoperfusion related to a systemic process, such as sepsis, blood loss, dehydration, or hypothermia. Arterial and venous sufficiency can be readily assessed at the bedside by examining the degree of capillary refill, tissue warmth, distal pulses, and the presence of bleeding at the cut edges of the wound.

Bacterial Burden

Normal wound healing mechanisms become impaired when the bacterial count in a wound exceeds 10 colony-forming units per gram of tissue.^{1,5,10} Exacerbating factors include a retained foreign body, the presence of necrotic tissue, and poor hygiene. Thorough irrigation and debridement can help prevent infection; antibiotics should be administered when an infection is either expected or suspected.

Contracture

Wounds close through the mechanism of contraction, but contracture may occur when normal, elastic soft tissue is replaced by scar, resulting in an aesthetic and functional abnormality. Any wound in a pediatric patient may lead to contracture over time. Examples include linear wounds or incisions over joints (where the development of a contracture can impair mobility), burns, and Volkmann ischemic contractures (attributable to muscle ischemia).

Hypertrophic Scars and Keloids

Hypertrophic scars and keloids result when the normal wound healing processes of proliferation and remodeling are exaggerated both in time and space, with too much dermal collagen deposited. Both are known to occur with greater frequency in the pediatric age group, with the incidence peaking in the second decade.^{11,12} Excessive scarring in children may result in decreased quality of life and can negatively affect psychosocial well-being and self-confidence.⁴

Hypertrophic scars are red, raised, dermal lesions that can develop after any form of tissue injury.^{13,14} They do not grow or extend beyond the border of the original wound, and the lesion is often well demarcated with a linear outline. Hypertrophic scars typically appear 4 to 8 weeks after injury, display rapid growth for up to 6 months, and resolve with time.¹¹ Clinically, hypertrophic scars can cause pruritus, especially when located on high-tension areas, such as the shoulder, neck, presternum, knee, and ankle, but tend not to be painful.¹⁴ Often the best treatment is to reassure patients and parents that the lesions will resolve without intervention. *Keloids* (derived from the Greek word *cheloides*, meaning “crab’s claw”) are raised dermal lesions that extend beyond the boundaries of the original wound.^{11,13,14} Histologically, keloids are composed of disorganized type I and type III collagen. Keloids may present years after the initial injury and may even develop spontaneously, particularly in areas of tension or in those patients who experience friction from clothes or accessories. Keloids are firm, shiny, pinkish-purple in color and may have telangiectasias. They too are well demarcated, but the borders are often quite irregular. The most common locations include the anterior chest, shoulder, earlobe, arms, and cheeks. Although keloids appear more frequently in individuals with darkly pigmented skin, investigators have not yet discovered a clear genetic pattern or a specific gene related to keloids. Like hypertrophic scars, they cause pruritus, but may also cause significant pain, burning, and hypersensitivity.¹¹

In a 2009 review, Juckett and Hartman-Adams¹¹ offered grade B recommendations (limited-quality patient-oriented evidence) regarding the treatment of hypertrophic scars and keloids: (1) Cryotherapy can be considered for smaller keloids and in combination with other treatments; (2) intralesional corticosteroid injections are appropriate first-line modality for the treatment of both keloids and hypertrophic scars; (3) pressure dressings can be used for the prevention of hypertrophic scars, particularly in the setting of burns; and (4) combination therapy is a second-line approach when first-line modalities fail to offer an improvement (for example, excision, silicone sheeting, or steroid injection).

Perhaps the most popular treatment is intralesional injection of triamcinolone (10 to 40 mg/ml, depending on location).^{11,15} This can reduce the size of the lesion and relieve some of the burning and itching. It should be administered with caution in pediatric patients because of the risks of adrenal suppression, depigmentation, and skin atrophy. Silicone sheeting has been used with variable efficacy.^{12,16} Excision of keloids is often disappointing because of the high recurrence rate (as high as 75%). Nevertheless, surgical debulking or total excision may be required for functional or aesthetic reasons.

Protein-Calorie Malnutrition

Suboptimal nutritional status impairs wound healing in infants and children. One should establish a baseline nutritional status in any child presenting with a wound; this includes asking about weight loss, dietary intake, food intolerance, and known illnesses.¹ Children with wounds in the setting of acute illness require aggressive nutritional supplementation for appropriate healing.

Vitamin Deficiency

Vitamins A, B, C, and K, zinc, copper, iron, magnesium, omega fatty acids, and the amino acids arginine and glutamine are essential for proper wound healing. Deficiencies should be identified and addressed.¹

Genetic Disorders

Inherited abnormalities in tissue architecture can negatively impact wound healing. Individuals with connective tissue abnormalities may heal more slowly, be more susceptible to injury, or demonstrate aberrant healing mechanisms. Examples of such disorders include Ehlers-Danlos syndrome, Marfan syndrome, and osteogenesis imperfecta (OI).¹ Ehlers-Danlos syndrome represents a spectrum of genetic defects characterized by abnormal production or processing of collagen. Common clinical findings reflect a lack of normal collagen and include hypermobile joints, hyperelastic, thin, and fragile skin, and blood vessel abnormalities. Marfan syndrome is an autosomal dominant disorder that results from an abnormality in fibrillin, which is essential for ECM formation. Clinical manifestations include joint hypermobility, hyperelastic skin, and aortic aneurysms with the risk of rupture. Finally, OI is characterized by a deficiency of type I collagen, and bone is most affected. There are multiple types of OI; in all types, wound healing may be delayed or impaired. A suspected connective tissue disorder in a child necessitates prompt referral to a geneticist, and wound management should be initiated with a multidisciplinary, specialized approach.

Diabetes

Both type 1 and type 2 diabetes mellitus can occur in children. One of the detriments to wound healing in patients with diabetes is local tissue ischemia and poor perfusion of the skin and subcutaneous tissue. Chronic diabetic wounds likely have more acute inflammation but relatively poor epithelialization, granulation, collagen proliferation, angiogenesis, and overall wound strength.¹⁷ It has been suggested that elevated hemoglobin A1c is associated with delayed wound healing; thus optimal glucose control is essential.¹⁸

Immunodeficiency

Inflammation and the immune response are part of normal cutaneous wound healing. Patients with acquired or inherited immunodeficiency are at increased risk of poor wound healing. Some examples of acquired immunodeficiency include the use of corticosteroids, chemotherapy, and infections, such as HIV. Inherited immunodeficiency syndromes that may contribute to abnormal wound healing in pediatric patients include chronic granulomatous disease, common variable immunodeficiency, and severe combined immunodeficiency. Neonates and infants have a less mature immune system than that of adults, which may precipitate infection, skin damage, and difficulties with wound healing.²

FETAL WOUND HEALING

In 1979, while studying limb amputations presumably attributable to amniotic banding, Rowlett¹⁹ observed that fetal cutaneous wounds can heal without forming scar tissue. This initial discovery was a catalyst for the scientific drive to characterize fetal wound healing at the molecular, cellular, tissue, and clinical levels.

Fetal skin undergoes a rapid period of development, beginning at week 3 of gestation, when the epidermis is first formed.²⁰ The epidermis becomes keratinized at week 14, is considered to have all components of mature adult skin at week 16 (for example, dermal appendages and basal layer), and throughout the remainder of the second and third trimesters, the skin undergoes further maturation to the point where it is felt to be identical to adult skin by birth²⁰ (Fig. 6-6). It is hypothesized that, up to at least week 26 of gestation, fetal wound healing is primarily regenerative (for example, scarless)⁷ (Fig. 6-7).

Fig. 6-6 Normal pediatric skin.

Fig. 6-7 Fetal wound healing compared to adult wound healing.

Differences in inflammatory cells and mediators, ECM (including collagen synthesis and deposition), and gene expression seem to account for many of the known differences observed in fetal and adult cutaneous wound healing.^{2,20-23} It was initially hypothesized that the ability of wounds to heal in utero without scarring was attributable to amniotic fluid, but we now know that there are intrinsic differences in fetal skin that allow it to heal without perceptible scars.^{21,24-27} Although there is a great deal of unknown regarding fetal healing, Table 6-2 lists the key characteristics of fetal wound healing that have been identified to date.

Table 6-2 Molecular, Cellular, and Tissue Differences in Fetal Healing Compared With That of Adults

Differences	Characteristics of Fetal Healing (compared with adult healing)
Inflammation ^{7,20,21,23,27}	
General response	↓ Inflammatory response ↓ Number of immune cells
Platelets	↓ Platelet degranulation
Cytokines	↑ IL-10 (blocks inflammation) ↓ IL-6 and IL-8
Neutrophils	↓ Adhesion molecule expression leads to ↓ neutrophil migration to wound bed ↓ Prostaglandins
Growth factors ^{7,20,21,28,29}	↓ VEGF (↓ inflammation and ↓ scarring) ↓ PDGF ↓ FGF ↓ TGF-beta1/↓ TGF-beta2 (↓ inflammation, ↓ scarring) ↑ TGF-beta3 (↓ inflammation) ↓ IGF-1
ECM ^{7,20,21,23,30-33}	
Fibroblasts	Fibroblasts act differently (produce collagen and proliferate simultaneously)
Collagen	↑ Total collagen ↑ Type III and IV collagen ↑ Type III:type I collagen ↑ Prolyl hydroxylase ↓ Collagen cross-linking Fine, reticular pattern of collagen deposition (compared with dense, parallel bundles)
HA	↑ HA, HA receptors
Proteoglycans	↓ Decorin, ↓ heparin sulfate ↑ Chondroitin sulfate ↑ Fibromodulin (blocks collagen fibrillogenesis, blocks TGF-beta)
Other	↑ MMPs (favor ECM turnover and remodeling)
Adhesion molecules ^{20,21,23,33}	↑ Fibronectin (attachment) ↑ Tenascin (migration)
Wound closure ^{21,22,28,34}	Myofibroblasts act quickly, briefly (if at all) ↓ Wound contraction (may be caused by amniotic fluid) ↑ Actin cables for closure
Cell-signaling transcription and gene expression ^{21,22}	Differences in phosphorylation ↑ Homeobox (Hox) gene expression regarding growth and proliferation

ECM, Extracellular matrix; *FGF*, fibroblast growth factor; *HA*, hyaluronic acid; *IGF*, insulin-like growth factor; *IL*, interleukin; *MMPs*, matrix metalloproteinases; *PDGF*, platelet-derived growth factor; *TGF*, transforming growth factor; *VEGF*, vascular endothelial growth factor.

Not all fetal wounds heal scarlessly. The degree of scar formation depends on several variables, including size (for example, larger wounds are more likely to heal with a scar), location (for example, skin versus intestinal tissue), species (scarless healing has been observed in fetal mice, rats, and humans; less so in fetal sheep and rabbits), and time (increased gestational age results in a lower likelihood of scarless healing).²⁰ Although there have been many important observations and discoveries regarding fetal healing on the molecular and cellular level, we have yet to acquire knowledge that significantly changes our clinical approach. The hope is that with time, the collective body of information acquired from fetal healing experiments will facilitate a clinical breakthrough in promoting scarless healing in both children and adults.

MANAGING WOUNDS IN INFANTS AND CHILDREN

Pretreatment Assessment

Wound prevention is an essential consideration in neonates and children, particularly in hospitalized patients. Because infant skin is thin and susceptible to tears and blistering, vigilant assessment for pressure injuries in the occipital region and from external objects, such as tracheostomies, gastrostomies, extremity and trunk braces, and wheelchairs, is paramount.³⁵ Frequent position changes (for example, every 2 hours) can help minimize friction and the risk of pressure ulcers.

Acute wounds are common in pediatric patients. As with any injury, the initial assessment prioritizes any life-threatening injuries and the ABCs (airway, breathing, circulation).¹ Hemostasis should be an initial goal with respect to soft tissue injury. A thorough history and physical examination in a pediatric patient should focus on the nature of the wound (acute versus chronic, the time course, mechanism of injury, degree of contamination, size, zone of injury, and presence of devitalized tissue). Other factors to be assessed include medical conditions, medications, previous injury or radiation, and social/family situation. Laboratory studies may be obtained if there is a suspicion of a systemic abnormality (for example, infection or malnutrition) or if there is hemodynamic instability. An initial workup for acute wounds often includes radiographs or other imaging (particularly for bites and penetrating, crush, degloving, and injection injuries), although one should be cognizant of the risks of radiation in children.

Wound Care Considerations

There are several mechanisms by which a wound in a child can heal. One way, as is often the case with surgical wounds, is primary intention (for example, primary closure). Delayed primary closure may be most useful when there is a great deal of tissue edema and in traumatic wounds in which there is questionable tissue viability.¹ Secondary intention involves allowing an open wound to close through granulation and reepithelialization. This can be performed with traditional dressing changes or by using NPWT. Skin grafts (either split-thickness or full-thickness) and/or flaps may be necessary when there is insufficient tissue coverage to facilitate adequate healing by primary or secondary intention.¹

Other considerations include the use of topical ointments and dressings, antibiotics, and tetanus and rabies prophylaxis.^{1,36-38} With respect to ointments and topical products, maintaining a moist healing environment is most important for optimizing granulation and epithelialization.³⁵ Most pediatric wounds do not necessitate antibiotic therapy if they are thoroughly irrigated and debrided. Exceptions include bites or penetrating wounds, grossly contaminated wounds, and perioperative antibiotic prophylaxis.³⁶ Tetanus prophylaxis should be administered to all children and adolescents whose vaccinations are not up to date or who have not yet received their full schedule of tetanus immunization.³⁷ Consideration should be given to the age of the child,

because specific formulations of tetanus vaccination may be indicated (for example, a booster containing tetanus toxoid as well as diphtheria toxoid and acellular pertussis)³⁷:

- Clean wounds: Tetanus toxoid is given if the child has received fewer than three previous doses or if the immunization history is unknown, or if it has been more than 10 years since the most recent booster.
- Grossly contaminated wounds and complex wounds: Tetanus toxoid and immune globulin are given if the child has received fewer than three previous doses or if the immunization history is unknown; tetanus toxoid should be given if it has been more than 5 years since the most recent booster.

Clinicians should be aware of the risk of rabies virus transmission in children exposed to “potentially rabid” animals, including dogs (uncommon in the United States), bats, foxes, skunks, and raccoons.³⁸ Prophylaxis against rabies virus should be considered for any wound (bite or nonbite) resulting from a raccoon, skunk, bat, or fox. Rabies immune globulin should be injected into the wound; the vaccine should be administered in all patients with suspected exposure.³⁸

In general, younger children are less able to communicate information about their injury and pain. Children are more likely to experience an adverse reaction to a product, because allergies are often undiagnosed earlier in life. Scars in children often remain pink and raised for a longer period than in adults; this should be communicated early and frequently to the patient and family to assuage anxiety regarding cosmesis and overall healing.

Wound Care Techniques

Particular techniques for wound care should be chosen based on the time course, location, severity, and mechanism of the wound. Bleeding should initially be controlled with pressure, packing, ligation, or cautery.¹ Pain and anxiety management is essential and may necessitate the use of intravenous opioids and/or anxiolytics. An effective regimen for moderate sedation in younger children is 0.02 to 0.05 mg/kg of midazolam and 0.2 to 0.75 mg/kg of ketamine. When possible, sedation should be performed by a certified specialist who is not the surgeon or wound consultant. Local anesthetics are effective, and additional doses can be given if needed; well-known maximum safe doses of lidocaine are 5 mg/kg without added epinephrine and 7 mg/kg with epinephrine.¹ Distraction techniques are recommended (for example, sucrose for babies, bubbles, lights, and electronic devices), and collaboration with a child life specialist, when available, is very valuable for the patient, parents, and surgeon performing the procedure.² General anesthesia may be required.

Thorough irrigation and debridement are required to cleanse and assess the extent of the wound, remove devitalized tissue, optimize healing, and prevent traumatic tattooing.³⁵ Irrigation should be performed with warm sterile water or normal saline solution.² Again, adequate sedation and analgesia are essential to minimize fear and discomfort, particularly in young children. Primary closure should be attempted whenever the wound is clean, viable, and has little tension. In children, the use of adhesive tapes (Steri-Strips) and skin glue can minimize the need for placing sutures. In infants and toddlers it is particularly important to use absorbable suture material that does not require removal. Either fast-absorbing chromic gut or 7-0 Vicryl is appropriate and will absorb quickly. When possible, wounds on the face should be closed with absorbable suture in children of all ages.

Vacuum-assisted wound closure has many applications and may be used in children.³⁹ Although its use has not been extensively studied in the pediatric population, several initial studies suggest that NPWT is safe and effective in children.³⁹⁻⁴⁴ NPWT offers the benefits of less frequent dressing changes, a clean wound environment, a compact system that facilitates return to activities of daily living, and often less pain, less edema, and possibly fewer operations with less extensive reconstruction.⁴² Multiple studies have estimated that NPWT may also be cost-effective compared with traditional dressing changes (the difference in cost is likely attributable to the cost of long-term nursing care).^{41,43} The literature varies with respect to the recommended pressure

setting: Naik et al⁴⁰ suggest the use of –50 to –100 mm Hg in infants, –75 to –125 mm Hg in toddlers and younger children, and up to –150 mm Hg in adolescents (as in adults). A setting as low as –20 mm Hg may be appropriate for neonates.⁴⁵ To minimize pain while the vacuum dressing is in place, continuous mode rather than intermittent mode should be used. Children may form granulation tissue at a faster rate than adults, and thus dressings may need to be changed more frequently (for example, every 24 hours).³⁵

Wound Care Dressings and Products

A plethora of dressings, topical agents, and wound care adjuncts is available for use with pediatric patients. The selection of dressings and topical agents should be individualized and reflect the characteristics of the wound in question, such as the presence or absence of infection, necrosis, exudate, moisture, damage to surrounding skin, granulation tissue, and exposed underlying structures.³ Dry and wet-to-dry gauze dressing changes have long been used for serial debridement and wound cleansing. However, the use of these dressings can be painful, especially for children. Many additional products, such as transparent films, nonadherent gauzes, hydrocolloids, hydrogels, hydrofibers, alginates, and foams, have occlusive and semiocclusive properties that provide moisture, remove exudate when necessary, minimize bacterial burden, and/or minimize pain. A comprehensive review of available products is beyond the scope of this chapter, but several referenced articles offer more detailed descriptions and evidence-based recommendations for clinical practice.^{2,3,35,46,47}

Medical grade honey is thought to be safe for use in pediatric patients, although rigorous efficacy studies in neonates and children are relatively limited.³ A Cochrane Review⁴⁶ that included 25 trials of the use of honey-containing products in acute and chronic wounds concluded that honey “might be superior to some conventional dressing materials,” although more research is required. Few studies have evaluated the efficacy of honey-based wound products in pediatric patients. Simon et al⁴⁸ reported their experience with Medihoney in 14 pediatric oncology patients; they stated that topical honey is a useful adjunct for wound healing in patients with immunosuppression.

Dressings and topical products containing silver (specifically nanocrystalline silver dressings, such as Acticoat) may be safe for use in neonates and children when clinically appropriate.^{3,49,50} However, there is concern about the possibility of silver toxicity, and more studies are needed to evaluate the effects of silver-containing dressings in children.^{2,3}

A systematic review of “modern” dressings and topical agents for acute and chronic wounds included 99 studies and found that hydrocolloids and foam dressings are probably efficacious in chronic wounds, and there is evidence to support the use of hydrofibers in acute wounds.⁴⁷ More rigorous scientific and clinical research is needed to better determine recommendations for the use of products containing silver, honey, HA, and activated charcoal, particularly in neonates, infants, and children.

Regardless of the method of wound closure, the use of skin barriers and barrier dressing, cream, or paste should be considered. These products minimize pain with dressing changes and reduce the risk of infection.³⁵ In addition, latex-free and hypoallergenic products should be used when possible.³⁵

Posttreatment Considerations and Complications

Regardless of the chosen method of wound closure or wound care, every effort should be made to keep the skin edges and sutures clean. An overlying dressing should remain in place for 24 to 48 hours to facilitate initial epithelialization. Wound infections may occur, necessitating the use of oral (and sometimes intravenous) antibiotics. Infants and children may develop hypergranulation in response to a wound, whereby granulation tissue grows beyond the boundaries of the

previous injury. This prevents epithelialization, may result in bleeding, and can be painful.³⁵ Topical triamcinolone cream for 1 to 2 weeks can be attempted to minimize hypergranulation.³⁵

Several techniques and products have been discussed to promote optimal scar healing. Sun protection is essential. Scar massage is easily taught to both children and parents; this involves applying pressure to soften scar tissue. Topical ointments and silicone sheeting can provide moisture and warmth to the evolving scar. A relatively new, adherent, silicone-based product, the Neodyne embrace Advanced Scar Therapy device, is applied to incisional wounds; it has been shown to improve the appearance of scars after abdominoplasty.⁵¹ Hypertrophic scar or keloid formation may occur in children, often requiring a multimodal approach to minimize irritation and improve cosmesis. Options include steroid injections, pressure garments, and excision, as discussed earlier in this chapter.

FUTURE DIRECTIONS

With respect to fetal healing, pediatric healing, and regenerative medicine, much has been discovered to date, but more basic science and rigorous clinical research is needed. Advances in tissue engineering, a better understanding of the role of stem cells, and the development of “ideal” biologic substitutes could revolutionize pediatric wound healing. A better understanding of the process of fetal healing may promote the development of improved techniques and indications for fetal surgery and may also facilitate the development of novel ways to promote scarless healing in children and adults.

KEY POINTS

- A thorough understanding of normal and abnormal wound healing mechanisms is important for optimal wound assessment and management in infants and children.
- The diagnosis of, differentiation between, and treatment algorithm for hypertrophic scars and keloids is an essential skill for any physician working with children.
- Compared with healing in adults, fetal healing is characterized by decreased inflammation, a more loosely organized and type III collagen, and different concentrations of ECM components (for example, more HA).
- An enhanced understanding of the dynamics of fetal wound healing will someday allow scientists and clinicians to replicate key fetal mechanisms in children and adults.
- Absorbable suture is recommended for wound closure in infants and young children.
- Perioperative wound care can optimize healing following many surgical interventions.

ACKNOWLEDGMENT

Fetal Surgery

Benjamin Padilla • William Y. Hoffman

etal diagnosis facilitated by imaging and fetal sampling has improved tremendously since the mid-1970s, allowing earlier and more accurate diagnosis of fetal anomalies. Surgeons are increasingly involved in the surgical management of these anomalies before birth. Most of these conditions are best managed expectantly, with definitive treatment after birth. However, some prenatally diagnosed conditions are progressive and can result in fetal death or threaten the well-being of the mother. Although some fetal therapies have resulted in great success, many others have shown little or no benefit.^{1,2} The current applications of fetal surgery are outlined in Table 7-1. Almost all fetal therapies are directed at lethal conditions, the most notable exception being myelomeningocele.

FETAL DIAGNOSIS

Fetal ultrasonography is the mainstay of prenatal imaging. Most anatomic surveys are conducted in the middle of the second trimester between 18 and 20 weeks' gestation. The accuracy of fetal ultrasonography depends on the skill and experience of the ultrasonographer and radiologist. Real-time fetal ultrasound identifies anatomic anomalies, provides physiologic information such as fetal heart rate, placental blood flow, and the presence or absence of fetal hydrops, and is critical for guidance during invasive fetal interventions. MRI is increasingly used when high-resolution fetal imaging is needed for the brain, spine, and body. Many syndromes are associated with congenital heart defects; thus fetal echocardiography is also an important diagnostic modality. The presence of a congenital heart defect precludes most fetal interventions.

Table 7-1 Potential Applications of Fetal Surgery

Indication	Anatomic Anomaly	Pathophysiologic Effects(s)	Treatment
Placental Vascular Anomalies			
Twin-twin transfusion syndrome	Unequal placental sharing; abnormal vascular connections	Fetal hydrops/death Surviving twin with severe morbidity	Fetoscopic laser ablation
Twin reversed arterial perfusion syndrome	Acardiac cotwin relies on normal cotwin heart for viability	High-output cardiac failure/hydrops	Selective reduction with RFA or umbilical cord ligation
Urologic			
Fetal obstruction uropathy	Lower urinary tract obstruction (e.g., posterior urethral valves)	Renal failure Pulmonary hypoplasia	Vesicoamniotic shunt
Thoracic			
CDH	Hole in the developing diaphragm	Pulmonary hypoplasia and hypertension	Tracheal occlusion
CPAM and pulmonary sequestration	Space-occupying lobar mass	Low-output cardiac failure Fetal hydrops/death	Maternal steroids Thoracoamniotic shunt
Tension hydrothorax	Lung hypoplasia	Pulmonary failure	Fetal lobectomy
Congenital high airway obstruction syndrome	Complete tracheal or laryngeal obstruction	Low-output cardiac failure/hydrops	Thoracoamniotic shunt Fetal tracheostomy or early delivery through the EXIT procedure
Cardiac			
Pericardial teratoma	Tumor mass compressing heart and great vessels	Fetal hydrops/death	Fetal sternotomy and resection
Pulmonary/aortic stenosis	Obstructed valves	Heart failure Single-ventricle physiology	Catheter-based balloon dilation
Ebstein's anomaly	Pulmonary compression from atriomegaly Pulmonic valvular atresia Tricuspid regurgitation	Fetal hydrops/death Pulmonary failure	Atrial reduction, valve repair
Neurologic/Posterior			
Myelomeningocele	Notochord malformation Chiari malformation	Hydrocephalus Neurogenic bladder/bowel Orthopedic anomalies Somatosensory loss	Fetal repair Fetal resection
SCT	Vascular "steal" through tumor mass	High-output cardiac failure/hydrops	

CDH, Congenital diaphragmatic hernia; CPAM, congenital pulmonary airway malformation; EXIT, ex utero intrapartum treatment; RFA, radiofrequency ablation; SCT, sacrococcygeal teratoma.

Biochemical screening is an important noninvasive diagnostic tool for evaluating aneuploidy. Noninvasive genetic testing for fetal disease is now possible with powerful sorting techniques that allow isolation of fetal cells and free fetal DNA from the maternal circulation.³ Fetal sampling remains an important method of karyotyping and DNA-based diagnosis of many genetic defects and inherited diseases. Amniocentesis provides a safe method of fetal sampling, but it cannot be employed until the second trimester. Chorionic villus sampling is increasingly being utilized, because it can be employed as early as 10 weeks of gestation.

FETAL ACCESS

The technical aspects of safely accessing the fetus for intervention evolved over 30 years of experimental and clinical work. In general, there are three methods for accessing the fetus:

1. Open hysterotomy
2. Minimally invasive fetoscopy
3. Percutaneous access

All three approaches require preoperative and intraoperative ultrasonography to define the anatomy, determine the position of the fetus, delineate the placental anatomy, and monitor fetal heart rate and umbilical artery blood flow during the operation.

The fetal surgery team generally consists of two pediatric surgeons, a maternal fetal medicine specialist, an ultrasonographer, and an obstetric anesthesiologist. The mother is supine with the left side down to minimize compression of the inferior vena cava. Depending on the nature of the intervention, maternal anesthesia can be either spinal or general. When needed, fetal anesthesia is administered through an intramuscular injection of an opiate and a nondepolarizing muscle relaxant.

Open fetal surgery requires general anesthesia, preoperative indomethacin, and high-dose inhalational agents to maintain uterine relaxation. Fig. 7-1 provides a summary of the open fetal surgery technique. The uterus is exposed through a low transverse abdominal incision. Ultrasonography is used to map out the placenta. A posteriorly positioned placenta allows an anterior hysterotomy. An anteriorly positioned placenta requires elevation of the uterus from the abdomen through a posterior hysterotomy. The hysterotomy is made with specially designed absorbable uterine staples that provide hemostasis and seal the membranes. The fetus is monitored with continuous pulse oximetry and echocardiography. Warm saline solution is continuously infused around the fetus to prevent hypothermia and compression of the cord vessels. Fetal exposure is limited to the body part of interest, and care is taken to prevent herniation of the fetus. After completion of the fetal operation, the fetus is returned to the uterus, the amniotic fluid is replaced, and the hysterotomy is closed with running and interrupted absorbable sutures. Postoperatively, tocolytics are administered and the mother is monitored for contractions. The fetal heart rate is monitored and daily echocardiography is used to monitor for ductus arteriosus constriction and right-sided heart failure.

Minimally invasive fetoscopic surgery is usually performed through a 3 mm fetoscope with a 1 mm working channel. Intraoperative real-time ultrasonography is critically important for identifying a safe point of access on the uterus that is free of large vessels and placental attachment. Furthermore, ultrasonography is an indispensable adjunct to fetoscopic visualization. Clinical applications of fetoscopic surgery include laser ablation of placental vessels in twin-twin transfusion syndrome, fetal cystoscopy and urinary tract decompression, division of amniotic bands, and tracheal occlusion for *congenital diaphragmatic hernia* (CDH). Percutaneous ultrasonographically guided interventions include catheter shunt placement (bladder and chest), radiofrequency ablation (RFA) of large tumors and anomalous twins, aspiration of fluid from fetal body cavities, and administration of drugs or cells directly to the fetus.

The *ex utero intrapartum treatment* (EXIT) procedure was developed as a bridge between fetal and postnatal therapy. Anesthesia is delivered to both the mother and fetus, and a hemostatic hysterotomy is made. The uterus is completely relaxed to prevent placental separation, and the umbilical cord is not clamped. In this way, the fetal circulation is preserved and the fetus is maintained on full placental support until the airway can be secured. The EXIT procedure has been used to reverse tracheal occlusion, repair the trachea, place a tracheostomy tube, resect large cervical tumors (Fig. 7-2), and to place cannulas for immediate *extracorporeal membrane oxygenation* (ECMO).⁴

Fig. 7-1 A, A hysterotomy is performed using a scalpel and suction. An opening of approximately 2 cm is created sharply. If possible, the dissection is carried down to, but not through, the membranes. B, The uterine stapler is applied. If kept extraamniotic, the risk of injuring a fetal part with the stapler is minimized. Two rows of hemostatic absorbable staples are applied, and the myometrium is cut between the two rows. C, An “amniotic bubble” appears after the myometrium is incised. Note the excellent hemostasis and the two uterine retractors. The membranes can now be opened sharply with scissors. An amniotic bubble cannot be created in all cases. Often the uterine cavity is opened at once. This is not a disadvantage, although extra care must be exercised to avoid injuring a fetal part or the umbilical cord when the stapler is applied.

Fig. 7-2 This fetus underwent delivery using the EXIT strategy. Note the large cervical teratoma that, on rigid bronchoscopy, was completely obstructing the trachea. A resection was performed while the fetus was on “placental support.” After the teratoma was excised, the trachea was intubated transorally, the umbilical cord was cut, and the fetus was “officially” delivered.

MATERNAL RISK

Fetal intervention places both the unborn patient and mother at risk. The mother gains nothing in terms of personal health benefits, but she is placed at significant risk for morbidity and potential mortality. Since the first open fetal surgery at the University of California, San Francisco in 1982, there have been no reported maternal mortalities.⁵ Despite technical advances in fetal intervention, disruption of the membranes and preterm labor are the Achilles heel of fetal surgery, resulting in premature delivery at approximately 34 weeks' gestation. Although fetoscopic techniques might theoretically mitigate maternal risk, the results of multiport fetoscopy have been disappointing, mostly because of membrane problems leading to preterm labor. The most common immediate maternal complication is pulmonary edema associated with the administration of tocolytics. Bleeding that requires transfusion is an infrequent but significant problem. Other complications include infection in the form of chorioamnionitis, pulmonary embolism, and deep venous thrombosis.⁴ Importantly, fetal surgery does not appear to diminish fertility or the ability to carry future pregnancies. However, the delivery of pregnancies after fetal surgery requires cesarean section because of the risk of uterine rupture.⁶

ANOMALIES AMENABLE TO FETAL SURGERY

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) interferes with normal lung development and is associated with 30% to 40% mortality as a result of pulmonary hypoplasia and pulmonary hypertension. Fetal ultrasound is used to stratify the severity of CDH. Liver herniation into the chest is the most important prognostic factor for isolated CDH, and is associated with markedly increased mortality.⁷ The *lung-to-head ratio* (LHR) was developed to further stratify the severity of CDH relative to lung size. The LHR compares lung size to head circumference to control for differences in gestational age and size. A fetus with liver herniation and an LHR of less than 0.9 has a very poor prognosis and is a candidate for fetal intervention.⁸

We hypothesized that in utero correction of the CDH and reduction of herniated abdominal viscera from the chest would allow antenatal lung growth and improved survival. Initial attempts at fetal surgery to treat CDH sought to correct the anatomic diaphragmatic defect in utero. Although CDH repair through open hysterotomy proved feasible, there was no survival benefit and this strategy was abandoned.⁹ Efforts were redirected at finding a strategy that promoted in utero lung growth. The observation that fetuses affected by congenital high airway obstruction developed hyperplastic lungs led to a series of animal experiments demonstrating that fetal tracheal occlusion stimulates lung growth. In 2003 the National Institutes of Health (NIH) funded a trial comparing in utero fetoscopic tracheal occlusion with standard postnatal care in fetuses with severe CDH.¹⁰ The tracheal occlusion group required an EXIT procedure at birth to remove the tracheal balloon. Although the tracheal occlusion group met survival expectations (73%) that were better than historical controls (37%), tracheal occlusion proved no better than standard therapy in the concurrent control group (77%).¹⁰

Fetal tracheal occlusion techniques continue to evolve. Temporary tracheal occlusion improves fetal lung volume, whereas long-term tracheal occlusion can be deleterious to type II pneumocytes. Temporary fetal tracheal occlusion can now be achieved with a tracheal balloon that is both deployed and later retrieved, using a percutaneous fetoscopic technique (Fig. 7-3). In utero removal of the tracheal balloon obviates the need for an EXIT procedure. The European experience with temporary fetal tracheal occlusion for severe CDH has been favorable, with survival of 50%. However, the dismal survival rate of 15% in the standard therapy group

Fig. 7-3 Using a single trocar, a perfusion endoscope with a working channel is inserted into the fetal mouth, and direct laryngoscopy is performed. After placing the endoscope into the midtrachea (facilitated by ultrasonographic guidance), a detachable balloon is deployed using a small catheter through the endoscopic working channel.

has come under criticism.¹¹ A prospective randomized trial of temporary fetal tracheal occlusion versus standard therapy is under way in Europe, and safety and feasibility testing of the device are ongoing in the United States.

Tumors

Fetal tumors are rare, and the vast majority of them are best dealt with postnatally. However, very large tumors can lead to fetal hydrops that results in fetal demise and thus they must be addressed in utero. Tumors cause nonimmune fetal hydrops by compressing the vena cava and compromising preload of the heart or from high-output cardiac failure through arteriovenous shunts within the tumor. Hydropic changes include pericardial effusion, pleural effusion, abdominal ascites, and scalp edema, as well as polyhydramnios and placental megaly.¹²

Congenital pulmonary airway malformation (CPAM), previously referred to as *congenital cystic adenomatoid malformation* (CCAM), is characterized by an overgrowth of the respiratory bronchioles with associated cyst formation. Although most CPAMs can be managed postnatally, very large CPAMs can result in fetal hydrops that rapidly progresses to fetal death. The size of the CCAM is the most important risk factor for developing fetal hydrops. The *CCAM volume ratio* (CVR), which describes the proportion of CCAM volume to head circumference, has been shown to be predictive of fetal hydrops.¹³ Microcystic CPAMs tend to grow until 26 to 28 weeks' gestation and then plateau or regress in size, whereas macrocystic lesions generally continue to grow throughout gestation. Fetal pulmonary lobectomy for CPAM with associated hydrops has been shown to reverse fetal hydrops, but it is associated with preterm labor and prematurity.¹⁴ Interestingly, mothers who were given steroids in preparation for fetal pulmonary lobectomy and who

Fig. 7-4 Twin-twin transfusion syndrome. Twin A is the donor twin, because its umbilical cord insertion is more centrally located than the recipient, twin B, whose cord insertion is more peripheral. The flow of blood is through the abnormal unpaired placental vessels.

then did not undergo the operation showed regression of the hydrops.¹⁵ Subsequent prospective studies showed that maternal administration of corticosteroids for large microcystic CPAMs is highly effective at reversing hydrops, whereas macrocystic CPAMs do not respond to corticosteroid administration.¹⁶ Macrocystic CPAMs with associated hydrops are best treated with percutaneous thoracoamniotic shunt placement.¹⁷ Fetal pulmonary lobectomy is now reserved for the rare patients in whom corticosteroids or thoracoamniotic shunting has failed.

Sacroccygeal teratoma (SCT) is another tumor that is commonly diagnosed prenatally. As with CPAM, SCT can result in fetal hydrops and death. SCTs can grow rapidly to an enormous size relative to the fetus. Attempts at ablating the tumor, either through alcohol injection or RFA, have proven unsuccessful. Fetal surgery to debulk the large external component of an SCT with associated hydrops has proven successful.¹⁸

Abnormalities of Twin Gestations

Monochorionic twins, identical twins that share a single placenta, can have problems with unequal blood flow or unequal sharing of the placenta. *Twin-twin transfusion syndrome* (TTTS) occurs in 10% of monochorionic pregnancies, and is the result of net blood flow from one twin to the other (Fig. 7-4). The “recipient” twin gets too much blood and is at risk of high-output cardiac failure, whereas the “donor” twin gets too little blood flow and is at risk of hypovolemia and hypoperfusion. TTTS carries a 90% mortality rate for both twins if left untreated. Fetoscopic laser ablation of the abnormal vascular communications between these twins has become the benchmark treatment for TTTS, with single and dual survivorship of 76% and 36%, respectively.^{19,20}

Twin reversed arterial perfusion (TRAP) *sequence* is a rare anomaly of monochorionic twins in which a normal twin acts as the “pump” for an acardiac, acephalic twin. As the acardiac, acephalic twin grows in size, the pump twin goes into high-output cardiac failure and hydrops. If left untreated, TRAP is associated with 50% fetal demise of the pump twin. Percutaneous ultrasound-guided RFA of the umbilical cord as it enters the abdomen of the acardiac twin has proved to be highly effective at halting TRAP and protecting the pump twin, with an overall survival of 80%.^{21,22}

Fig. 7-5 Intraoperative surgery for a fetal thoracolumbar myelomeningocele. Note the four hysterotomy retractors and the catheter that provides continuous warmed irrigation fluid to the fetus during the operation.

Myelomeningocele

Myelomeningocele (MMC), or *spina bifida*, is a devastating birth defect resulting from an open neural tube and exposed spinal cord. The rationale for in utero repair of MMC is that the exposed spinal cord becomes secondarily damaged by amniotic fluid exposure, direct trauma, and hydrodynamic pressure. Various animal models demonstrated that in utero repair of MMC prevents this secondary injury and results in improved neurological function.^{23,24}

MMC is the first nonlethal anomaly for which fetal surgery was undertaken.²⁵ Early attempts at fetal MMC repair in humans showed promise, but it was difficult to know the true benefit when compared with historical controls. The NIH funded a multicenter randomized trial (Management of Myelomeningocele Study [MOMS])²⁶ comparing fetal MMC repair at 19 to 26 weeks' gestation with postnatal repair (Fig. 7-5). The study ended early because of the superiority of fetal surgery. Fetal MMC repair reduced the need for ventricular shunting for hydrocephalus at 12 months (40% for the fetal group versus 82% for the postnatal group, $p < 0.001$) and improved motor function, including the ability to walk at 30 months of age (42% for the fetal group versus 21% for the postnatal group ($p < 0.01$)).²⁶

IN UTERO STEM CELL TRANSPLANTATION FOR GENETIC DEFECTS

With the advent of chorionic villus sampling, various inherited genetic defects can be detected early in gestation. A number of these defects, such as immunodeficiencies, hemoglobinopathies, and storage diseases, are potentially curable with in utero hematopoietic stem cell transplantation.²⁷ Before 15 weeks' gestation, the fetus is in a preimmune state, and the bone marrow is primed to receive hematopoietic stem cells migrating from the liver. Thus in utero transplantation may avoid problems with rejection, tolerance, and graft-versus-host-disease that occur with postnatal transplantation.²⁸ However, delivery of even a small volume of cells to the fetus early in gestation is technically demanding and carries significant risk. Furthermore, it is unclear whether a sufficiently high degree of engraftment can be achieved for a cure. Although transplantation for severe combined immunodeficiency syndrome has been successful, the promise of in utero stem cell therapy for other disease has yet to be fulfilled.

PLASTIC SURGERY AND FETAL INTERVENTION

Early intervention for congenital deformities of the head and neck or limbs has similar appeal to in utero stem cell treatment: the potential to reverse secondary deformities by correcting the

inciting problem. The finding that the fetus heals without visible or histologic scarring before approximately the middle of pregnancy makes the repair of cleft lips and other congenital deformities particularly attractive.

Scarless Healing

Early in the process of developing fetal surgery, the observation was made that the fetus heals without scarring up to the middle of the second trimester, which is roughly the middle of the pregnancy. This is obviously intriguing, because a cleft lip, for example, might be repaired leaving no visible scar. Improved prenatal ultrasonography allows the diagnosis of clefts and other craniofacial anomalies by 20 weeks' gestation, which would be early enough for scarless healing. A better understanding of the mechanism of scarless healing might also allow alteration of the wound healing milieu in the postfetal environment to improve or even eradicate scar. Despite extensive investigation into the nature of fetal wound healing, the process remains poorly characterized.²⁹ Many differences in specific markers have been elucidated between the fetal and adult wound-healing environments,³⁰ but attempts to induce fetal healing in the adult environment have been generally unsuccessful. It appears that the ability of fetal wounds to heal without scarring is intrinsic to the fetal epithelial cell rather than the amniotic environment, making it more difficult to apply to the adult situation.

Cleft Lip And Palate

Intrauterine cleft lip repairs have been performed in both large and small animals. Smaller animals such as rat and rabbit models allow inexpensive interventions, but because of their very short gestation, these can be seen primarily as proof of concept.^{31,32} The primary model for fetal cleft lip repair has been in sheep; there is not a reliable large animal model for clefts, necessitating surgical creation of the cleft lip and alveolus. In addition, sheep have proved to be tolerant of intrauterine interventions without the preterm labor that is precipitated in primates, including humans.

Initial efforts at fetal cleft repair used an incisional model, performing repair at the same time.³³ Later a two-procedure model was used to more closely simulate the clinical situation, creating the cleft surgically at approximately 60 days gestation, and then repairing the cleft at a second procedure at approximately 90 to 100 days.³⁴ A subsequent investigation compared neonatal repair with in utero repair in the long-term recovery of fetal lambs (6 months). This showed that both groups had some lip shortening that would require secondary surgery (and therefore an adult-type scar); however, the group repaired in utero did not have maxillary growth inhibition, which was a significant and unfavorable finding in the postnatal repair group.³⁵

The development of endoscopic techniques for fetal intervention (also known by the term coined by Harrison, *fetendo*, because of the similarity of its manipulation to a video game) was performed in the hope of decreasing preterm labor, although this has not been the result, as previously mentioned. Endoscopic repair of cleft lips a number of years ago was limited by the small space for maneuvering and the large instruments designed for laparoscopic surgery.³⁶ In the future, robotics with multiple degrees of freedom at the end of the instrument may allow much more accurate endoscopic intervention. Alternatively, better control of preterm labor with tocolytics may facilitate more open intrauterine procedures.

Craniosynostosis

Craniosynostosis of either single or multiple sutures is generally best treated early. There is a large body of evidence that strip craniectomy alone is effective if performed early enough. We created a fetal model for unilateral coronal craniosynostosis by placing a mixture of bone

morphogenetic protein (BMP) and TGF-beta into a cranial defect in a fetal lamb. This produced a phenotype analogous to that in humans, with flattening of the frontal region on the affected side and compensatory bossing on the contralateral side.³⁷ In a subsequent study we returned after 3 to 4 weeks to perform strip craniectomy of the stenosed side and showed that the phenotypic findings were all reversed.³⁸

Although fetal intervention for craniosynostosis may not be currently practical in humans, these articles indicate that it may eventually be possible to perform an earlier minimal intervention that will reverse some of the late findings seen in these complex craniofacial anomalies.

Amniotic Bands

Amniotic bands have been implicated in limb abnormalities ranging from indentations in the extremities to intrauterine amputations. In addition, they have been proposed as a cause of orofacial clefts.

Experimental work, again in sheep, showed that a suture or umbilical tape around an extremity could produce an amniotic band “type” outcome, and that early release of the band would reverse those findings.³⁹ In another study our group demonstrated orofacial clefting, similar to that found in humans when a tie was placed intraorally to the lateral face.⁴⁰

The fact that a severe deformity can result from a single band led to the conclusion that a simple endoscopic release of the band could reverse the outcome. This has now been accomplished in numerous people with good results.^{41,42}

KEY POINTS

- Most congenital anomalies are managed expectantly during pregnancy, with definitive treatment after birth.
- Fetal surgery is largely reserved for fetuses with lethal anomalies, the notable exception being fetal MMC repair.
- Experienced multidisciplinary teams are essential for the success of any fetal therapy program.
- NIH-funded prospective randomized trials have shown the benefit of fetal surgery in MMC and TTTS.
- The future of fetal therapy lies in stem cell and genetic therapies for the correction of genetic defects in utero.
- Improved techniques of endoscopic intervention and control of preterm labor after fetal intervention may permit broader application for congenital deformities.

Cutaneous Lesions

Julia Corcoran • Bruce S. Bauer

utaneous lesions are common in children and are a source of concern for parents, pediatricians, and surgeons alike. Fortunately, most of these lesions are benign. Despite this fact, many patients seek surgical removal of the lesions. For parents and older children, the visibility of the lesion and teasing by peers are frequently factors that prompt a desire for removal. In particular, fear of future malignant degeneration is a motivating force among families and physicians alike. The role of the pediatric plastic surgeon is to educate the family and referring physician about the nature of the lesion so they can make an informed decision regarding the need for removal, balancing this with appropriate expectations for the scar that will follow. If excision is recommended, the pediatric plastic surgeon must suggest the best timing with respect to the natural history of the lesion, the physical and social development of the child, and how the operative site and reconstructive plan might be affected by subsequent growth. Finally, the plastic surgeon should remove the lesion with appropriate margins for the type of lesion and in the most aesthetically pleasing manner possible.

In this chapter we will discuss the issues that must be considered when excising skin lesions in the pediatric population and focuses on the specifics of commonly occurring cutaneous and subcutaneous lesions. The discussion is divided into melanotic and nonmelanotic lesions. Hypertrophic scars, keloid scars, neurofibromas, and vascular lesions are covered in Chapters 6, 11, and 37.

TIMING OF SURGERY

Most skin lesions in children can be removed electively, leaving the timing of surgery to a mutual decision between family and surgeon. Parents of infants and preschool children with lesions in visible places such as the face, arms, and legs may have concerns about the social stigma for the child and may desire removal of these before he or she reaches school age. Parents concerned about the risks associated with anesthesia may want to defer surgery to a time when removal could be performed with a local anesthetic. Families concerned about malignant degeneration

may have an unwarranted sense of urgency. These family biases should be balanced against the child's ability to cooperate with both the planned procedure in the office and postoperative limitations and care.

Office sedation of children can be difficult because of their size and the need for weight-appropriate doses of sedatives and reversal agents. Office procedures are better conceived of as local anesthesia cases. Other situations requiring sedation are best performed in a surgical center or operating room with the assistance of anesthesia personnel. These limitations mean that most infants and toddlers are not candidates for office procedures. Most cases in which local anesthetic is used should not be attempted until the physician can engage the patient in meaningful conversation. Some children are ready for office surgery at 4 to 5 years of age, whereas others are not ready until much later. The patient's motivation and verbal skills are the best indicators of patient selection for office surgery.

Despite the low acuity of most pediatric cutaneous lesions, the energy and time that can be expended assessing and treating these smaller, benign cases can be quite significant. Parents often come to the pediatric plastic surgeon's office with preconceived notions of what should happen. Families with a history of skin cancer or melanoma often are overly concerned about malignancies in their children. Many come with the misconception that plastic surgeons can operate without leaving a scar or hold hope that lasers and other types of treatment will remove the scar secondarily. The surgeon must realistically describe the balance of a scar versus the visibility of the lesion and encourage the parents to be realistic about the perceptions of a scar versus the lesion in the child's later interaction with peers. Parental guilt and anxiety about scars, visible lesions, or previous medical care can be palpable at times.

The surgeon must also be sensitive to how each child reacts to the possibility of having surgery awake versus being asleep. If the child is clearly distressed about being awake during the procedure, the surgeon can allow the family to delay surgery until the child is old enough to be comfortable with surgery in the office or can clearly state that he or she would prefer to be asleep. The surgeon is the advocate for the young child; if the child is clearly uncomfortable having surgery awake, the surgeon should work to prevent the child's being pushed into it by a parent.

A clear conversation with parents and older children is essential, in age-appropriate language and covering all of these points. Expectations for the quality of scars on different body parts should also be discussed in advance with families. Certain areas such as the jawline, shoulders, and presternal chest are more prone to hypertrophy. Scalp wounds will have areas of residual alopecia. Areas over extensor surfaces such as the back and joints tend to spread over time. Skin grafts, even if well done, will have the appearance of a patch and may be associated with regional contour deformities. Prediction of these events is easier than explanation in retrospect. This information should be reinforced with further meetings and possibly teaching sessions with the nursing staff when staged or complex reconstruction, such as with tissue expansion, is considered. If the family's expectations for the procedure differ from the surgeon's, these generally straightforward cases can weigh one down with unhappy patients who have unrealistic demands. It is important to discuss the postoperative course, including activity limitations and the necessity for active scar management and sun protection. Most of these procedures are elective and can be scheduled around family, school, sports, and patient and surgeon schedules.

EXCISIONS: CAVEATS AND SUGGESTIONS

Although most technical details of excising lesions in children are similar to those in adults—planning incisions to lie favorably, taking adequate margins, undermining surrounding tissue to relieve tension, meticulous hemostasis, and exact realignment of the dermal-epidermal junc-

tion—there are several unique situations that may catch a surgeon off guard whose practice is predominantly with adult patients.

Juvenile skin, although elastic, does not have the laxity of adult skin afforded by gravity. Local head, neck, and extremity flaps that are easily achievable in adults are often difficult in children. Secondary pull on adjacent structures must be anticipated before planning local flaps. When direct excision and primary closure are not possible, the surgeon should entertain other strategies, such as staged excision and skin grafting. If local flaps remain the most desirable form for wound closure, regional tissue expansion can provide the needed tissue and diminish secondary deformation, if the flap is rotated or transposed. Direct advancement might distort the adjacent structures or limit later growth. Free tissue transfer can be used for larger lesions, with or without expansion (see Chapter 12 for more details).

Infantile skin is very thin, seemingly paper-thin at times. Generous undermining, even for small lesions, is essential to prevent sutures from pulling through. Reverse cutting needles also seem to reduce laceration of the dermis in subcuticular suturing. The use of precision-tip blades (Beaver-type 6700 and Bard-Parker 15C style) provides increased control over cutting corners of very small excisions in infants and children.

Patient selection and advance planning are the keys to office excisions with the use of local anesthetic in children. Children amenable to in-office surgery are those whom you can engage in conversation. “Talkaesthesia” is critical to leading the child through the procedure. Calm, straightforward parents are also essential. Children who sense parental anxiety will be unable to cooperate. We favor the use of topical anesthetics such as LMX and lidocaine/prilocaine (EMLA) to diminish the pain of the needle stick and injection of the local anesthetic. Using fine-gauge needles (27-gauge or 30-gauge) and buffering with sodium bicarbonate solution (4 parts local anesthetic with epinephrine to 1 part sodium bicarbonate solution) also help to decrease the sting. Comparing the sensation to the “tingling when your hands or feet fall asleep” is an explanation most children and parents can understand. The surgeon should prepare and drape the area widely to provide ample room to work and use operating room–quality instruments.

The surgeon should also place sutures that do not require great effort to remove. We prefer to use buried dissolvable sutures, and the senior author (BSB) prefers to use pull-out Prolene sutures. We discourage the use of chromic sutures in cosmetically sensitive areas; they do not dissolve rapidly enough to avoid epithelialized tracks. Furthermore, the erythema and induration induced by the cellular mechanism of suture resorption can create concern about wound infection. However, chromic sutures are excellent for all skin repairs on the ears and on the palms and soles, where epithelial and suture tracks seem not to be an issue.

The surgeon should keep dressings simple—Steri-Strips or Dermabond. Acetaminophen (Tylenol), ibuprofen (Motrin), and ice packs should help with postoperative discomfort. The need for postoperative analgesia seems to diminish significantly when either a regional nerve block or periincisional injection is performed with bupivacaine (Marcaine); 0.25% is injected before completion of the procedure. Management of postoperative pain expectations by honest explanations in age-appropriate language is helpful to the patient and parent. For small excisions in the office, we compare the postoperative expectation to a cut from a fall at the park—an event that most children know they have survived.

Postoperative wound management can be challenging in this patient population. Patient and parent education about the natural history and duration of scar maturation can diminish concern about the considerable period of palpable healing scar ridge and pink discoloration (up to 12 to 18 months). Although most parents are willing to perform uncomfortable scar massage on themselves, they often cannot bear to “hurt” their children. Taping with Steri-Strips, Microfoam tape, or over-the-counter silicone sheeting can be helpful. The use of small external dressings for

toddlers and infants should be limited to hours when the parents are watching the child to decrease the risk of the child's removing the bandage and choking on it.

In this era of children with heavily committed schedules of sports and other activities, parents and children, who frequently see missing these activities as catastrophic, must be counseled, often by talking to the child to emphasize that he or she must choose a surgery time that will allow an appropriate break from these activities. It is essential that the surgeon and nursing staff emphasize the importance of limiting activity in the postoperative period to minimize the risk of wound complications and again clarify what is acceptable and what is unacceptable activity. For elective procedures it is often worth delaying surgery until the "off season," even if it means a narrow window of time before the next sports season begins.

MELANOTIC LESIONS

Congenital Melanocytic Nevi

Congenital melanocytic nevi (CMNs) are generally referred to as birthmarks. Although they may be apparent at birth, many gradually become more apparent over the first few years of life as pigmentation increases (tardive appearance). Physical examination reveals that they are plaques, raised from the surrounding skin with increased skin markings and appendages. They can range in color from a tan to a deep blue-black. Neural elements with rugose texture and coarse terminal hair may be present. Surface texture and color may change over time, particularly near puberty, and are not necessarily indicative of malignant change. Some of these lesions will lighten with time and may present with a halo phenomenon during puberty.¹

Embryologically, these tumors are hamartomas consisting of nevus cells, which differ from regular melanocytes by their arrangement into nests or clusters, their rounded dendritic shape, and their tendency to keep their melanin pigment rather than to transfer it to surrounding epithelial cells.² Histologically, the presence of nevus cells within the eccrine ducts and glands, follicular epithelium, or blood vessels is specific for CMNs, but these findings may not be seen in all congenital nevi.³ In larger lesions, nevocytes can be found within subcutaneous fat and, rarely, deeper structures.

CMNs have been classified by their current size or the predicted adult size. In adults, small nevi that have a diameter of 1.5 cm or less are present in approximately 1:100 people. Medium-sized lesions measure between 1.5 and 19.9 cm in diameter and have an occurrence rate of 1:1000. Large lesions are larger than 20 cm and have a reported occurrence rate of 1:20,000 births. A subset of large lesions is the giant nevi, which have a diameter larger than 50 cm and an occurrence rate of 1:500,000 (Fig. 8-1). Although this classification has been used for both prognostic and reconstructive purposes, a more descriptive classification could be more predictive. A new consensus-based classification has been proposed and accepted that includes categories for projected adult size, location, satellite count, and morphologic characteristics (color heterogeneity, rugosity, nodularity, and hypertrichosis).⁴

The reported lifetime risk for melanoma in small and medium CMNs is low, ranging from 0.7% to 2.4%.² Melanoma with small and medium lesions typically occurs postpubertal. Therefore prophylactic removal of small and medium lesions is recommended anytime before puberty, particularly if the lesions are located in areas of irritation (for example, the collar line, belt line, or bra line), if they cannot be easily observed for changes (for example, when on the scalp or the posterior aspect of the body), or if they are in cosmetically sensitive areas. The expected scar must be balanced against the benefits of removal. Small lesions, if favorably located, can be excised and

Fig. 8-1 CMNs occur in a wide variety of sizes, colors, and surface characteristics. **A**, A child with a giant nevus and multiple satellite nevi on his scalp has the variety of small and medium CMNs that present as satellites. **B**, Typical appearance of an isolated medium CMN on the neck. **C**, Medium synchronous or “kissing nevus” of the upper and lower eyelid shows how both the nevus cells migrated into the developing eyelid before its separation, and how a medium nevus may require more than simple excision for treatment. **D**, Congenital giant pigmented nevus with marked variegation in surface color, nodularity, and proliferative nodules.

closed primarily in layers. Medium lesions require more thoughtful reconstruction, including serial excision, grafting, tissue expansion, and local flap coverage (Figs. 8-2 and 8-3).

Even with the low risk of degeneration, these smaller lesions can still be the source of significant peer ridicule, and thus excision may be appropriate before these issues become a major source of psychological distress for the child and family.

Large and giant lesions present more of a management and reconstruction challenge. The immediate concerns are for potential malignancy and the psychosocial development of children with large, obvious lesions. Although the exact occurrence rate is unknown, Tromberg et al³ reported melanoma rates of 4.5% to 10% in large and giant nevi. Older studies reported that 60% of melanomas that arise from large CMNs do so in the first 3 years of life, with 70% occurring by puberty.⁵ When melanoma arises, it may not always be from the nevus itself. Without a prospective, randomized trial, the best evidence for malignancy risk remains population studies.

Fig. 8-2 A, This small CMN is in a very visible area of the girl's face. It was treated relatively early, starting at 3½ years of age. B, Appearance after two stages of excision spaced 3 months apart. C, Appearance 12 years after excision.

Fig. 8-3 A, This medium CMN was excised in two stages to minimize tension and overall lengthening of the scar. B, Appearance 1 year after completion of the excision.

A recent Danish population study confirmed the small but real increase in the lifetime risk for developing melanoma in patients with large CMNs.⁴

Further confounding the prognosis of large CMNs is the potential for leptomeningeal involvement, in particular for lesions located over the axial central nervous system. MRI can diagnose the so-called *neurocutaneous melanosis* accurately, but its significance with regard to the development of later melanoma in patients without central nervous system symptoms remains obscure.⁶ However, baseline MRI studies are prudent and can sometimes be predictive of neurologic outcomes.⁷ Understanding that deeper seats of tumor generation likely remain with the patient even after removal of a skin lesion, these surgeries should be considered tumor debulk-

ing rather than complete removal. Periodic lifetime follow-up with these patients will reveal the true nature of the lesion. With these thoughts in mind, early reconstruction is still recommended. Functional and aesthetic outcomes should direct the extent of reconstruction to optimize the physical and psychosocial development of the child.

Many strategies have been tried for removal and reconstruction of large and giant nevi. Serial excision can often debulk these massive lesions but can rarely completely remove them. Because of their size, excision and split-thickness autografting have generally had poor functional and aesthetic outcomes. Dermabrasion, curettage, and laser treatment have problems with the reappearance of the remaining deeper nevus cells, continued risk of degeneration, and difficulty following the lesions for malignant transformation because of scarring. Even in patients in whom these surface treatments have been successful in lightening the nevus, it does not affect the tendency for some of the lesions to thicken and show heavy hair growth. The long-term effects of laser treatment on the remaining population of nevus cells must still be determined, but some experimental data suggest that it may put these cells at additional risk of degeneration.^{8,9}

We have begun staged excision and reconstruction in full-term infants as young as 6 months of age. Given the typical depth of nevocytes in congenital nevi, the excision is carried out to the level of the fascia to avoid nevus recurrence. To fill the deficit with like tissue, tissue expansion is the mainstay of reconstruction for large and giant CMNs of the head and neck, torso, and proximal limbs in our practice. We have selectively used free tissue transfer in combination with expansion to allow primary closure of donor sites or to secondarily expand free flaps in the extremities or over the neck and shoulder (shawl) areas. We favor full-thickness skin grafting over the dorsum of the hands and feet. Tissue expansion can also provide large full-thickness skin grafts with easy donor-site closure, increasing the amount of full-thickness graft available¹⁰⁻¹² (Figs. 8-4 and 8-5). In the periorbital area, we have previously reported the use of expanded supraclavicular grafts, but we now graft upper and lower eyelids separately with postauricular nonexpanded grafts. The surgical details can be found in Chapter 22.

Fig. 8-4 A, This infant with a giant CMN of the back had excision and reconstruction with nonmeshed, split-thickness skin grafts. B, The result 1 year after excision. This is one location on the trunk where excision may still yield a reasonable aesthetic outcome, whereas wrapping a graft around the flank and onto the abdomen can result in significant long-term deformity. C, The result 15 years after surgery still shows reasonably good contour and aesthetics.

Fig. 8-5 A and B, This infant had a giant nevus of the upper back, chest, flank, and anterior trunk adjacent to the breast. C, The first round of tissue expanders during expansion and just before first-stage excision. D and E, At surgery with the second round of expanders at 2½ years of age. F, Result 4 months after second-stage excision.

Fig. 8-5, cont'd G and H, A final expansion was done at age 9½ years of age to reduce scars and most of the remaining nevus lateral to the breast. I and J, Result at 11 years of age with a small area of nevus on the breast awaiting breast development before the final phase of excision.

Satellite lesions can be as large as or larger than solitary lesions, and thus excision may be warranted (Fig. 8-6; see also Fig. 8-1, B). The decision to excise satellite nevi needs to follow the previously discussed considerations, with some being excised specifically to limit the stigma that may be associated with them. Often we combine removal of the satellite lesions when we remove or reconstruct the primary lesion. Older children, who have been through previous surgeries for a large or giant nevus, are quite capable of understanding the pros and cons of additional surgery/scar and may often help make these decisions. Occasionally, changes in satellite lesions can be evaluated easily with punch biopsies rather than complete excision, avoiding some of the limitations associated with recovery from more significant surgery.

Fig. 8-6 Typical appearance of multiple satellite nevi associated with a giant nevus of the trunk. Larger satellites may be excised in early childhood in areas in which the skin may be more elastic early. Others can be followed and excised only if the child expresses concerns about the aesthetic appearance when older.

Given the prevalence of certain patterns of distribution for large and giant nevi, we have found that the planning of each stage of excision and reconstruction can be readily outlined and the expectations for the number of surgeries, expected orientation and appearance of scars in each body area, and caveats for each body region are readily outlined.

Blue Nevii

Blue nevi can be congenital but are more likely to present as smooth-domed, dark blue-black acquired nevi in the head, neck, or extremities; they occur more commonly in females. Because of the dark coloring and acquired status, concern about malignancy exists. Two histologic variants are known: the common blue nevi, which tend to be smaller and well demarcated, and the cellular blue nevi, which tend to be larger and have irregular borders and spindle-shaped melanocytes (Fig. 8-7). Both lesions are considered benign, but malignant cellular blue nevi have been reported, and thus removal is recommended.

Café-au-Lait Spots

Café-au-lait spots are well-demarcated light tan to brown macules that can be present in normal individuals or, when multiple, can be a marker of neurofibromatosis (Fig. 8-8). The texture and adnexal distribution within the macules are normal. The color may fade over a lifetime. Histologically, the keratinocytes contain macromelanosomes with increased pigment. Because of the normal quality of the skin and benign nature of these lesions, surgery is rarely recommended. Laser treatment can be considered when a lesion is present in cosmetically sensitive areas, but both recurrence and success have been reported.¹³

Fig. 8-7 The deep and heavy pigmentation of a blue nevus creates the characteristic blue appearance. **A**, The lesion may appear as a more typical isolated smaller lesion. **B**, It may also appear as in this rare large blue nevus involving the entire ear.

Fig. 8-8 **A**, Café-au-lait lesions may be seen as single, large, uniformly pigmented lesions on the trunk or occasionally on the face. **B**, They may also appear as multiple smaller lesions associated with neurofibromatosis type 1.

Rarely, large and giant deeply pigmented café-au-lait spots may occur in the facial area that may warrant excision. In these cases it must be made clear to the parents (or the child, if old enough) that the lesion itself carries no risk of degeneration. The benefit may come from aesthetic improvement rather than medical necessity. The family must be comfortable with the likely results of such surgery and feel that the end result is preferable to the café-au-lait macule. In these situations there is a benefit to referring these patients for initial treatment or at least testing with a laser.

Fig. 8-9 The nevus spilus, also known as a speckled lentiginous nevus, looks much like a variable area of café-au-lait pigmentation behind varied freckles, spots of pigment, or even an atypical CMN or a blue nevus. This child presented with a lightly pigmented nevus spilus with darker pigmentation. The lesion gradually darkened throughout, making the border of the lesion more distinct.

Nevus Spilus

The *nevus spilus*, also known as a *speckled lentiginous nevus*, looks much like a café-au-lait spot but has darkly pigmented areas within it, which may represent freckling, a CMN, or a blue nevus (Fig. 8-9). Suspicious areas within the nevus should undergo biopsy, and if the lesion is in a cosmetically sensitive area, complete excision can be done. Nevus spilus may on occasion be large or giant, with sizeable areas of CMNs within the boundaries. A decision may be made to selectively excise these darker areas while leaving the greater area of light pigmented lesion untreated, particularly when the larger lesion encompasses areas in which surgical scars may present later problems of a cosmetic or functional nature (for example, the perianal or genital region) (Fig. 8-10).

Mongolian Spots

Mongolian spots are blue-gray pigmented patches that present in newborn infants, particularly in Fitzpatrick type IV to VI skin types. They primarily present over the lumbosacral area but can be anywhere over the back of the body. Histologically, the melanocytes responsible for the lesion are located in the lower two thirds of the dermis. These lesions generally regress spontaneously by 3 to 4 years of age, and no surgery is indicated (Fig. 8-11).

Nevus of Ota and Nevus of Ito

Nevi of Ota and *nevi of Ito* are blue-gray to brown macules located in the distribution of the first and second trigeminal nerve branches (Ota) (Fig. 8-12) or in the shoulder area (Ito) (Fig. 8-13). All structures in the area can be involved as seen with mucosal and retinal pigmentation with nevi of Ota. They are primarily found in the Fitzpatrick IV and V skin types and are more frequent in females. Bilateral presentation can occur (10%), and concurrence with Mongolian spots has been reported. Like Mongolian spots, they represent atypical pigmentation with normal skin adnexa; however, they do not resolve over time. Although present at birth, the pigmentation may not become obvious until puberty or pregnancy, when they tend to darken. In general, these lesions are considered benign, but the development of areas of malignancy has been reported. Many modalities have been used for treatment, but laser therapy seems to be the most successful, especially with Q-switched ruby, Q-switched alexandrite, and Q-switched Nd:YAG lasers.¹⁴

Fig. 8-10 A, Nevus spilus may also present as a giant nevus with medium and large CMNs within the lightly pigmented borders. Because of both the size and marked variability of pigmentation and surface character, the managing pediatric dermatologist in this case thought that the lesion would be difficult to follow for potential changes. A decision was made to excise as much of the entire lesion as possible. B, Completion of the first tissue expansion. C, After the first excision and advancement of the expanded flaps. D, The patient is shown 2½ years after one additional expansion and excision. The remaining area of nevi is more uniform and easier to follow. Selected remaining small CMNs may be excised and closed primarily.

Fig. 8-11 Although Mongolian spots are possible in the upper back, shoulders, and extremities, they are most typically found in the lumbosacral region.

Fig. 8-12 A nevus of Ota typically presents as a blue-gray to brown macule located in the distribution of the first or second trigeminal nerve branches.

Fig. 8-13 A nevus of Ito presents as a blue-gray to brown macule located in the scapular and deltoid region.

NONMELANOTIC LESIONS

Spitz Nevus

Sophie Spitz¹⁵ originally reported this lesion in 1948 when she observed the generally benign course of lesions in children that appeared histologically similar to melanoma. Her report noted only one occurrence of metastasis in 13 cases.¹⁵ This conundrum regarding the diagnosis of Spitz tumor continues today. Clinically, the lesion typically presents as a rapidly growing, well-demarcated pink nodule with flaky skin coverage, but pigmented Spitz nevi also occur (Fig. 8-14). They can be listed in the same differential diagnosis as pyogenic granuloma. Local recurrence is a concern, and occasionally in-transit nevus cells have been noted in patients with multiple recurrences. A recent survey of practice habits of surgical dermatologists supports conservative reexcision with 2 to 3 mm margins after shave-and-punch biopsy.¹⁶

Histologically, these lesions are melanocytic nevi with specific patterns of atypia. There can be a diagnostically challenging area of crossover with melanoma that can be difficult for the pathologist to differentiate. Terms such as *Spitzoid melanoma* and *atypical Spitz nevus* should key the surgeon into the pathologist's discomfort with the diagnosis. When concern about the possibility

Fig. 8-14 Spitz nevi have a variable appearance. These lesions are commonly a pinkish nodule that is well demarcated and rapidly growing. **A**, This early lesion demonstrates the flaky skin surface that may also be seen. **B** and **C**, Typical pink, firm, plaquelike Spitz nevi—one on the cheek and one on the ankle. **D**, Pigmented Spitz nevi are also seen and may be confused with melanoma during visual examination.

of melanoma persists, consultation with outside dermatopathologists is useful. Sentinel lymph node biopsy has been suggested at the time of further excision in atypical Spitz nevi. However, the practice has not proved useful, and current recommendations are for clean margins and observation.¹⁷

Nevus Sebaceous

Sebaceous nevi (of Jadassohn) are seen in newborns as waxy pinkish-orange hairless plaques, usually in the scalp and face, and fall within the family of epidermal nevi (Fig. 8-15). Most lesions are isolated, but linear coup-de-saber–like lesions and extensive multiple lesions may indicate underlying ocular and central nervous system defects with associated developmental delay, seizure disorder, and sebaceous nevus syndrome (Fig. 8-16). The *cutaneous lesions* are hamartomas of malformed sebaceous units. During childhood the lesions are quiescent, but they tend to become verrucous and irritated at puberty. Reports of benign and malignant neoplasms developing within sebaceous nevi during adolescence populate the literature. Basal cell carcinoma and syringocystadenoma papilliferum are the most common neoplasms cited, with a small percentage degenerating to squamous cell carcinoma. Removal is recommended for both prophylaxis of all types of neoplasia (not necessarily cancers) and elimination of a site of irritation. The more extensive lesions also present with considerable aesthetic deformity, and treatment may at times be planned well before puberty to avoid the associated stigma that may be associated with their presence.

Although some extensive lesions have been treated with a variety of lasers, this treatment approach only temporarily manages the crusting and irritation and will need to be repeated throughout life. Surgical excision, if timed and staged appropriately, can excise even extensive lesions. In these cases we have begun serial expansion in the first year and typically combine expander placement in regions of large and giant lesions with excision and primary closure, or we stage serial excision (without expansion) for narrower linear lesions.¹⁸ Although some surgeons

Fig. 8-15 A, Sebaceous nevi are common in the scalp and facial area and vary in appearance, but typically are waxy, pinkish-orange lesions with absence of hair. B, Although some are not as elevated and distinct as seen here, the lesions often become more distinct as the individual reaches puberty.

Fig. 8-16 A and B, This infant had extensive sebaceous nevi but did not have the seizures typically associated with giant multiple lesions and sebaceous nevus syndrome. C and D, Staged excision was carried out with a combination of tissue expansion and linear partial excisions with primary closure. Here two of the expanders are in place. E-G, Approximately 6 years after first-stage surgery.

have expressed concerns about the healing of intralesional excisions, we have not found any differences in healing compared with that of pigmented nevi, if care is taken to avoid undue tension on closure. Broad-spectrum antibiotic coverage is used routinely in these cases.

Epidermal Nevi and Epidermal Nevus Syndromes

Epidermal nevi are raised, keratotic lesions that often appear in infancy and may continue to define their borders and thicken until adolescence and adulthood, making complete excision difficult in younger children. The lesions may be pigmented or flesh-toned. Like nevus sebaceous, epidermal nevi are hamartomas of skin and skin appendages; unlike nevus sebaceous, there is no predilection for neoplasia. Multiple variants exist, including the verrucous epidermal nevus (Fig. 8-17), inflammatory linear verrucous epidermal nevus (ILVEN) (Fig. 8-18), nevus comedonicus (Fig. 8-19), and Becker's nevus (Fig. 8-20). They can be isolated lesions, but when multiple or particularly large, one must be suspicious that they may be part of one of the multiorgan syndromes jointly known as *epidermal nevus syndromes*. These syndromes have ocular, neurologic, skeletal, and possible renal and cardiac anomalies associated with extensive or multiple epidermal nevi that follow the lines of Blaschko.¹⁹

Patients present for treatment of epidermal nevi because of their unsightly appearance and symptoms, such as irritation and pruritus. Multiple modalities for treating epidermal nevi have been reported, including multiple laser modalities and cryotherapy. Anecdotally, there appears to be an increased risk of hypertrophic scarring in cases of surgical excision. One specific variant for which surgery may be indicated is ILVEN (see Fig. 8-18). This is an intensely pruritic,

Fig. 8-17 A and B, Epidermal nevi are raised and keratotic lesions that are present during infancy and become more distinct as they thicken and become more keratotic, particularly toward adolescence. In this patient topical and laser treatments were not successful in relieving discomfort associated with the lesion, and excision was carried out, aided by tissue expansion. C and D, Immediate postoperative views after excision.

Fig. 8-18 ILVEN are commonly treated with topical medication and lasers. However, extensive lesions may be unresponsive, and patients may be “crippled” by severe pruritus and pain. **A**, As seen in this 3-year-old boy, the lesion is less distinct than the epidermal nevus in Fig. 8-17, but it may become equally plaquelike over time. Excision of ILVEN, with direct closure, skin graft, or tissue expansion, is curative. **B**, Completed tissue expansion in the adjacent thigh. **C**, Immediately after surgery. **D**, Result 1 year after excision.

Fig. 8-19 This patient has a giant area of nevus comedonicus with areas of active abscess, comedones, and pitted scar.

Fig. 8-20 Becker's nevi present most commonly as an area of pigment similar to café-au-lait spots, although with less distinct margins and heavy hair growth. These lesions are most common in the upper chest, shoulder, and upper arm.

pink, irritated lesion that weeps and crusts, is more common in females, and often is located in the lower extremity, buttocks, and perineum. There is diagnostic and treatment overlap between ILVEN and linear psoriasis. Some patients may respond or partially respond to topical agents, laser therapy, and psoriatic treatments. Failure to control the debilitating pruritus is an indication for surgical therapy, particularly those lesions in the perineal, perianal, and genital area. Patients can be totally relieved of their symptoms with excision. Unlike melanocytic lesions where small gap areas may be infiltrated with nevus cells, these segmental linear lesions can be interspersed with normal skin. Often these lesions are extensive, and planning may include excision with direct closure, skin grafting, or expanded flap reconstruction. If the full width of the lesion can be excised and closed directly or with a local flap, treatment may be accomplished in a single surgery. In other cases, several nonadjacent lesions may be excised at one procedure and remaining strips of nevus removed in a subsequent procedure. Larger lesions may require tissue expansion in the course of treatment. It is the senior author's (BSB) experience that whether young or old, these patients are some of the most grateful patients you care for, and this treatment can have far reaching benefits for the child.²⁰

Pilomatrixoma, Pilomatrixoma, or Calcifying Granuloma of Malherbe

The *pilomatrixoma* is a benign neoplasm arising from hair follicle matrix cells with a predilection to appear in areas of fine vellus hair in children. This is the most common “acquired cyst” in the pediatric population. The brow and sideburn areas of the face are particularly common sites. It presents as a hard mass fixed in the skin, often with a bluish hue or telangiectasia overlying it. Secondary infection, possibly from picking at it, is not an uncommon occurrence. These lesions grow gradually over time and rarely regress spontaneously. As they enlarge the overlying skin progressively thins, often requiring larger skin excision for uncomplicated healing (Fig. 8-21). This alone suggests some benefit of early, although certainly not urgent, treatment. Excision is recommended.²¹ When completely excised, recurrence is rare, but some patients present with second or third lesions in different areas of the face.

Fig. 8-21 A, A typical pilomatricoma, or calcifying granuloma, presents in the head and neck area as a firm cyst fixed within the skin, with a bluish-pink area of telangiectasia overlying it. In this case there is a 2 cm lobulated cyst fixed at the area of the mandibular angle showing as two points of discoloration on the overlying skin. B, A surface telangiectasia over a lesion, as in this lower medial cheek lesion, is a common development. C and D, This adolescent presented with multiple lesions that progressed rapidly to raised cystic appearances, which in some areas became inflamed, infected, and then drained.

Juvenile Xanthogranuloma

Juvenile xanthogranuloma presents as both acquired and congenital lesions in the faces of children. They initially appear as a pink nodule that becomes yellowish. Many resolve spontaneously within 1 year, but some require as much as 3 years before resolution (Fig. 8-22). If a diagnosis is made clinically, observation is warranted; however, the rapid growth of these lesions often leads to biopsy before a diagnosis is made. Histologically, they are composed of giant cells and histiocytes and are not granulomas at all. We have reported a patient in whom the orbicularis muscle was infiltrated with giant cells and histiocytes.²² Muscle infiltration has been described previously in rare truncal lesions. Rapidly growing, more infiltrative lesions may warrant early excision (Fig. 8-23). For smaller, highly visible lesions that have not resolved after 1 year, a decision may be made with the family and the child when he or she is old enough to understand the pros and cons of excision and the resulting scar to excise rather than wait for possible resolution.

Fig. 8-22 A typical juvenile xanthogranuloma presents either as a pink single nodule or multiple nodules that become yellowish, may ulcerate, and then involute. This child had just the single facial lesion.

Fig. 8-23 A and B, This infant presented with a congenital single xanthogranuloma that enlarged to involve half of her chin. During surgery it was discovered that this lesion infiltrated the underlying muscle, a phenomenon that, at the time this was reported, had only been seen with large truncal lesions. C, Appearance 3 months after excision and primary repair. D, Long-term results at 6 years of age.

KEY POINTS

- CMNs carry a small but real risk of melanoma over a lifetime. In cosmetically sensitive areas or if they cannot be easily observed, removal is recommended at an appropriate age.
- Tissue expansion can be used “primarily” to enlarge and allow transposition and translocation of local and regional flaps. Expansion can also be used “secondarily” to provide larger areas of full-thickness skin graft and to allow free tissue transfer by facilitating direct closure of the donor site. Whether used for primary or secondary purposes, tissue expansion can improve aesthetic outcomes from reconstruction of large and giant CMNs by replacing tissue with like tissue.
- Spitz nevi are benign lesions with a propensity for local recurrence. Histologically, they can be difficult to differentiate from melanomas. Review of the specimen by a qualified dermatopathologist is recommended. Sentinel node biopsy is not indicated.
- Sebaceous nevi carry a small but real risk of developing neoplasia within the lesion during the second decade of life. They also may become verrucous and quite irritated. Removal is recommended, with the timing dependent on the size and location of the nevus.
- Epidermal nevi are benign and usually can be managed with laser ablation. Before surgical resection in younger children, families should be reminded that these nevi might continue to develop. Anecdotally, hypertrophic scarring can occur after resection of these lesions, which can be problematic.
- When multiple or extensive epidermal nevi or sebaceous nevi are noted, a workup is appropriate to determine whether there is syndromic involvement of other organ systems.
- Surgical excision is not generally recommended for café-au-lait macules and Mongolian spots. The color of these lesions tends to fade, and the skin’s quality and texture are normal.
- Laser therapy is the mainstay of treatment for nevi of Ota and nevi of Ito.

Acute Pediatric Burn Injury

Sandhya Deo • Joel Fish

Children are not little adults, and the differences in acute burn care for adults and children are notable. This chapter focuses on these differences and emphasizes that pediatric acute burn injury is a unique area requiring special knowledge of resuscitation, sepsis, infection control, prevention strategies, wound care, analgesia, and early rehabilitation. The long-term consequences for rehabilitation and surgical reconstruction are beyond the scope of this chapter and are discussed later in the book.

The age at which patients are no longer considered “pediatric” varies. Most agree that patients in the later stages of adolescence (14 to 16 years of age) should be considered for treatment in a pediatric versus an adult facility. Specialized pediatric burn care requires trained health personnel who can dose medications appropriately, adjust fluids, and provide necessary analgesia and sedation. Nursing and rehabilitation staff should understand developmental milestones through adolescence to ensure optimal patient care. Many adult burn care facilities have partnered with pediatric specialists to work together on the smaller population of pediatric burn patients, effectively combining their care. We think that pediatric burn patients *must* go to a pediatric facility where specialized pediatric burn care is available.

EPIDEMIOLOGY AND BURN PREVENTION

Burns are a common injury in children,^{1,2} who are naturally curious, impulsive, and active. In developed countries most injuries are small and relatively easily managed.^{3,4} However, burns are the third highest cause of accidental death in children (after motor vehicle accidents and drowning).⁵ Pediatric burns occur most commonly in the home and while children are unsupervised.^{6,7}

In the United States, approximately 500,000 burns occur annually requiring medical attention,⁸ and half are thought to be in children.⁹ In North America, pediatric burns are primarily scald injuries in the youngest age groups (younger than 5 years of age), and most occur in males;

the incidence of flame burn increases as children approach adolescence but does not reach adult numbers until they are older than 20 years of age.^{10,11}

Third world countries have a higher incidence of pediatric burns.^{6,12,13} In underdeveloped countries, malnutrition and infectious diseases, coupled with limited resources, result in high mortality rates and severe outcomes of permanent disability.^{14,15} Although the numbers are largely not known, the World Health Organization estimates the rate of child deaths from burns is more than seven times higher in low- to middle-income countries than in high-income countries.¹⁶ The lack of prevention efforts in underdeveloped countries partially explains the high rates of pediatric burn injury.¹⁷

Documenting the specific causes of pediatric burn injury is of great interest, because many injuries are preventable. The long-term impact of scarring can be significant, especially in children younger than 2 years of age, accounting for the current push to eliminate pediatric burns through education and legislation.¹⁸ Scald injuries can be reduced but are unlikely to be eliminated as long as children have access to hot beverages.

Some childhood burn injuries have been prevented because of the introduction of flame-retardant clothing, safer cooking practices, school-based fire awareness programs, education by burn prevention committees in local communities, and raised awareness of the dangers.¹⁸⁻²⁰

In North America and Europe, major pediatric burn injuries are rare; this might be explained in part by prevention efforts over the past 20 years.²¹ The decreasing incidence of major pediatric injury has resulted in difficulty maintaining competency and expertise of all burn team members to treat major pediatric burn patients. Many burn care centers struggle to ensure an adequate volume of pediatric injuries to maintain the required competency necessary for obtaining burn center verification by the standards of the American Burn Association. The use of modern telecommunication may help to link regional centers and aid lower-volume centers in maintaining pediatric burn care, preventing the need for parents and children to leave their community to receive even basic burn care.

Specialized causes of burn injury, such as chemical and electrical injury, in the pediatric population are rare in developed countries. They account for less than 1% of admissions to burn centers.²² Pediatric trauma and burn injury combined is rare.²³

ACUTE INJURY ASSESSMENT

First Aid

Basic first aid treatment applied immediately and for the correct period of time has been shown to decrease the degree of burn injury. First aid includes removing the child from the burning stimulus, removing the clothing, and cooling the burned area with cold, running water.²⁴ Caregivers might forget these simple steps in a moment of panic, and some have inadequate general first aid knowledge.²⁵ Education workshops are available for new parents. Many local burn centers that treat pediatric burn injury teach basic first aid to first responders as an effective way to reach those at risk.

The basic three steps of initial management of a pediatric burn injury are as follows:

1. The circumstance and mechanism of burn injury are assessed.
2. The burn extent is assessed.
3. The depth of the injury is assessed.

Determining the Circumstances of the Injury

Determining the circumstances of the injury in pediatric patients is imperative. Pediatric burn care providers need to understand the developmental milestones from birth to 3 years of age.

Many accidents occur at the onset of a new developmental milestone; burn injuries can occur if home care providers are caught off guard. For example, if children who are learning to pull themselves up are left alone for a few moments, they might be found upright, having reached a steaming cup of liquid and pulled it onto themselves. Knowledge of developmental milestones is essential for another reason. Therapists need to adjust their goals accordingly for children who require prolonged care over a number of weeks. Parents need to be informed that often their child will temporarily stop advancing until the acute burn injury has been treated.^{6,26,27}

Understanding the specific circumstances surrounding pediatric injury is critical in screening for neglect and abuse. Reported rates of nonaccidental injury vary among burn centers, and this is an important determinant when deciding whether to admit children with burn injuries.^{2,4,7,9} The advantage of having access to a pediatric center with a team that handles cases of suspected child abuse and neglect is that a separate team of investigative health care members can perform this function. The burn team can proceed without the circumstances of the injury affecting the provision of care. Thus the treating burn team members are not directly involved in managing the domestic situation, allowing them to maintain an ongoing, trusted relationship with the parent in a difficult situation.

Burn Depth and Extent

The relative body surface area (BSA) of a child differs from that of an adult. In children, the head is a larger proportion and the lower limbs are a smaller proportion than in adults. Methods of estimating the BSA in children include the pediatric Rule of Nines, using the palm of the child's hand as 1%, and age-specific Lund and Browder charts.^{28,29}

The basic classification of burn depth is the same for adults and children regardless of age. Accurate assessment of the extent and depth soon after the burn occurs (within the first 72 hours of injury) is frequently problematic. Most burn injuries are scalds, which can take 10 to 14 days to declare the full extent and depth of the burn. The burn depth generally is more difficult to determine in children than in adults.

The classification of burn depth based on a clinical examination within the first 72 hours of a scald injury has a low accuracy (60% to 70%).^{4,9} This leads to many issues regarding basic care models used for pediatric injuries. Burns from a scald mechanism rarely result in a perfectly uniform pattern. The pattern will typically have areas of splash marks and evidence of gravitational flow, depending on the position of the child. This can lead to an inaccurate diagnosis of the burn depth in the initial assessment in the emergency department or walk-in clinic. Superficial injuries from scald burns can be apparent for hours and may manifest as a red, painful, and blanching area. This may be completely resolved within 12 hours of the injury, adding to the unpredictable overestimation of the burned area.

The burn extent is a major factor that determines the need to triage a patient to a formal burn care center. Triage guidelines are used throughout the developed world, with minor variations in the criteria.³⁰⁻³² Most agree that a patient whose burn covers more than 20% BSA requires urgent triage to a burn care program (and typically to an intensive care–capable center for pediatric patients). Smaller injuries (10% to 20% BSA) require specialized burn care but are not as likely to require urgent intensive care monitoring. Patients whose burn covers less than 10% BSA (which describes most of the pediatric burn injuries in the developed world) require specialized burn care providers. However, they rarely need intensive care support unless they are extremely young (younger than 6 months of age) or have pediatric comorbidities that place them at risk of complications related to burn care, such as a seizure disorder, neurologic disorder, or severe developmental delay.

FLUID RESUSCITATION

The most common indication for fluid resuscitation is a burn extent beyond 20% BSA and/or full-thickness (deep) burns of more than 10% BSA. Small children younger than 1 year of age may require fluid resuscitation, including those with a burn size of less than 10% BSA, because they are particularly susceptible to the systemic consequences of an inflammatory burn injury. Crystalloid is the fluid of choice. The role of colloids in pediatric burn resuscitation is unknown, and these are not currently recommended for children with burns smaller than 20% BSA.³³

The basic pathophysiology that leads to intravascular fluid loss after a thermal injury is similar to that in adults. Fluid replacement is required. The fluid should be as isotonic as possible and should contain sodium and a buffering agent. However, children are unique in their ability to actively secrete antidiuretic hormone in response to injury; therefore they differentially retain sodium, causing water to be preferentially retained and a *hyponatremic state* to develop. This common early electrolyte abnormality is seen in pediatric patients within the first 24 hours of resuscitation. Slow correction with an intravenous saline solution helps to resolve most of the hyponatremia within 24 hours. Oral fluid restriction is never required for burns of less than 20% BSA in the absence of renal dysfunction, because hyponatremia will self-correct.

Children who weigh less than 30 kg require maintenance fluid *in addition to* resuscitation fluid, as calculated by the modified Parkland formula (4 ml/kg/% BSA).^{33,34} For children *younger than 1 year of age*, maintenance fluids ($D5\frac{1}{2}$ NS) should be added according to the body weight. Dextrose is necessary to prevent hypoglycemia, because their glycogen stores are limited. A Foley catheter is inserted in all children with burns *greater than 15% BSA*, and an hourly urimeter is attached. Intravenous fluids are adjusted each hour according to the previous hour's urine output.^{33,34} In patients whose involved BSA is less than 15%, oral hydration and the continuation of breast-feeding are appropriate sources of fluid^{34,35} (although an IV line is often needed for analgesia).

The calculated ongoing requirements for fluid are often based on urine output alone for most burn patients with less than 20% BSA, with a target of 0.5 to 1.0 ml/kg/hr. Many guidelines indicate that output in pediatric patients should be 1.0 ml/kg/hr, whereas other centers routinely consider 0.5 ml/kg/hr as adequate, especially for cases with 15% BSA or less.^{33,34} Awareness of so-called fluid creep is essential. This describes the increased use of fluids because of high levels of narcotics and sedation, resulting in excessive fluid resuscitation and higher levels of abdominal and extremity compartment syndrome.³⁶ Although abdominal compartment syndrome in children has been reported, these children have extensive burns (greater than 75% BSA). Major burn injuries in which levels of fluid resuscitation approach 250 to 300 ml/kg/hr require special consideration, because these rates will not be sustained in pediatric patients.

Pediatric patients with major burn injuries require a central line, which may necessitate a specialized pediatric care unit and ultrasound guidance. Intraosseous lines can be used to temporize until definitive access can be established. Pediatric intravenous access is often a challenge in burn patients with limited available sites, where access is difficult even in experienced hands. For this reason alone, patients may be transferred to a pediatric facility where pediatric anesthetists and image-guided therapy are available.

Another nuance of treating pediatric burn injury is that, although prophylactic intubation for a burn size of more than 20% BSA is recommended for safe transport and care, often scald burns of 20% BSA can be managed in an intensive care environment with careful observation. If the fluid requirements are not high, then intubation can be avoided.³⁴ Many major pediatric burn injuries are overestimated, and the depth can often take longer than 72 hours to manifest. Flame burns in children are less common than in adults and generally result in full-thickness burn injury requiring higher levels of fluid for initial resuscitation.

PAIN CONTROL AND SEDATION

Burn injury can be intensely painful, and children especially benefit from early, adequate analgesia. This alleviates trauma and anxiety for the child and helps to facilitate ongoing treatment. Evidence indicates that multimodal therapy is most useful in pediatric burn patients.^{37,38} This includes acetaminophen, nonsteroidal antiinflammatory drugs, and the judicious use of opiates. Other medications such as methadone, gabapentin, and clonidine may be helpful but should be given only after discussion with a pediatric pain service.

Providing adequate analgesia and sedation in a controlled environment is crucial for procedures performed on the ward or in an outpatient facility, including cleansing the burn surface, debriding loose skin and blisters, and/or applying dressings. Most pediatric burn centers have their own protocol for pediatric sedation, which generally involves an opiate and a benzodiazepine.

Distraction or play therapy, for example, with toys, books, bubbles, or TV, can be used as an adjunct to decrease a child's anxiety and perception of pain.³⁸

NUTRITION

Good nutrition is imperative to optimize wound healing in all burn patients. Early oral feeding is encouraged but can be problematic in children, in part, because of the resultant gastric paresis and ileus. In this situation, nasogastric or nasojejunal tube feeding should be considered. Enteral nutrition is preferable to parenteral nutrition when possible. Early enteral nutrition preserves the mucosal integrity of the gut and improves intestinal blood flow, which prevents bacterial translocation and infection.^{39,40}

Burn injury leads to a hypermetabolic state, and a child's nutrition needs to be adjusted accordingly. The age of the child, the size of the burn, and other underlying comorbidities should be considered. Pediatric dietitians can assist in calculating the recommended daily caloric intake, with an appropriate carbohydrate/protein ratio.³⁸⁻⁴⁰

Pharmacologic agents that can reduce the hypermetabolic response include analgesics, anabolic hormones, anabolic steroids, and catecholamine antagonists. The use of insulin and/or metformin in children to stabilize blood glucose levels is well described.^{40,41} Oxandrolone, an anabolic steroid, is reported as effective for burns involving more than 50% BSA. In acute burns, oxandrolone in children has been shown to reduce hospital stay, maintain lean body mass, improve body composition, and improve hepatic protein synthesis.^{40,42-44} Supplementing vitamins and essential minerals (iron, zinc, and copper) is beneficial.⁴⁵

Children should be weighed regularly to ensure that their nutritional requirements are being met. Small children younger than 2 years of age grow at a rapid rate, and metabolic derangements have been measured for more than a year after major burn injury. Most small and moderate-sized burns do not cause the same metabolic consequences as larger burn injuries; nevertheless, supplemental feedings are needed to maintain caloric requirements.

WOUND CARE

The principles of pediatric burn management focus on promoting wound healing and easing patient discomfort. They include the following:

- Minimizing bacterial contamination
- Providing an optimal wound environment
- Ensuring adequate tissue perfusion
- Minimizing negative effects of inflammation
- Promoting reepithelialization

- Providing adequate fluid management and nutrition
- Providing adequate pain relief

After assessment, the wound or wounds are swabbed then cleaned with warm, soapy water. Debridement of any loose, devitalized skin is ideal if tolerated by the child. The wounds are then dressed. Many dressings are available. The choice varies according to the wound. In children, long-term dressings are warranted to minimize the trauma of dressing changes. Some of the available dressings are listed in Box 9-1.

The following areas in children warrant particular attention:

- The head and face
- The hands and fingers
- The feet
- The perineum
- Healed areas of skin (which require regular gentle moisturizing)

The introduction of slow-release-silver-containing products over the past 10 years has resulted in the use of a closed technique for many scald injuries. Silver products can provide sustained topical antimicrobial activity against gram-positive and gram-negative species for up to 1 week. With this treatment, many patients with burns of 15% BSA or less are managed as outpatients, as long as the pain is controlled and the dressings are used correctly. Our experience with the closed dressing technique has revolutionized care for pediatric scald injury patients, allowing early discharge, with no change in the rates of surgery or in the low rates of wound infection (Fig. 9-1). The products require proper use and need to be applied early (less than 72 hours after an injury) to be effective before the wounds are colonized. Many burn units stock one to three silver products for children. Fig. 9-2 provides a flow sheet for using the closed dressing technique. Tables

Box 9-1 Dressings Available for Pediatric Burn Patients

- Silver sulfadiazine (SSD)/Flamazine: SSD is a silver-containing cream that can be applied directly to a burn wound, with or without an outer dressing. Flamazine contains SSD and chlorhexidine for additional antimicrobial activity. The cream should be applied directly over the burn area daily. Old cream is removed before the wound is cleaned and new cream applied.⁴⁶⁻⁴⁸
- Bactigras: A Vaseline mesh gauze impregnated with chlorhexidine that provides a simple nonadherent antibacterial dressing. It requires a secondary outer dressing to hold it in place. The dressing should be changed relatively frequently (1 to 3 days).⁴⁹
- Mepitel: A porous, semitransparent mesh made from a flexible polyamide net coated with a soft silicone layer. The nonstick nature makes it ideal in children. It requires an outer dressing but can be left in place for several days if exudate is minimal.⁵⁰
- Aquacel Ag: A cellulose dressing impregnated with low-dose silver. The fibrous material absorbs exudate and allows the silver ions to be readily released. The amount of exudate will determine the frequency of dressing changes required.⁵¹
- Mepilex Ag: A nonadherent foam dressing designed to protect the wound and absorb exudate. It is composed of a hydrophilic polyurethane foam with a soft silicone inner layer and a waterproof outer layer.⁵²
- Acticoat (3 or 7 days): A nonadherent wound dressing that delivers a low concentration of silver for antisepsis. It comprises a layered mesh coated with nanocrystalline silver and an inner rayon mesh. The silver ions are activated with water.^{47,53}
- Biobrane: A semipermeable synthetic dressing made of collagen-coated nylon bonded to silicone. It facilitates fibrovascular tissue growth into the inner layer and provides a temporary bacterial barrier. It is usually applied in the operating room under sterile conditions, left intact until the wound reepithelializes. As the Biobrane lifts off, it is trimmed away. Biobrane has been shown to reduce pain and shorten healing time.⁵⁴

Fig. 9-1 In a historical matched-control study with 50 cases in each group, a closed-dressing technique was compared with the use of daily dressings with Polysporin or Flamazine. Results demonstrated the impact on the length of stay in a cohort of 3-year-old (average) children with an average burn size of 5% BSA. Favorable outcomes similar to these have been reported in many pediatric units.

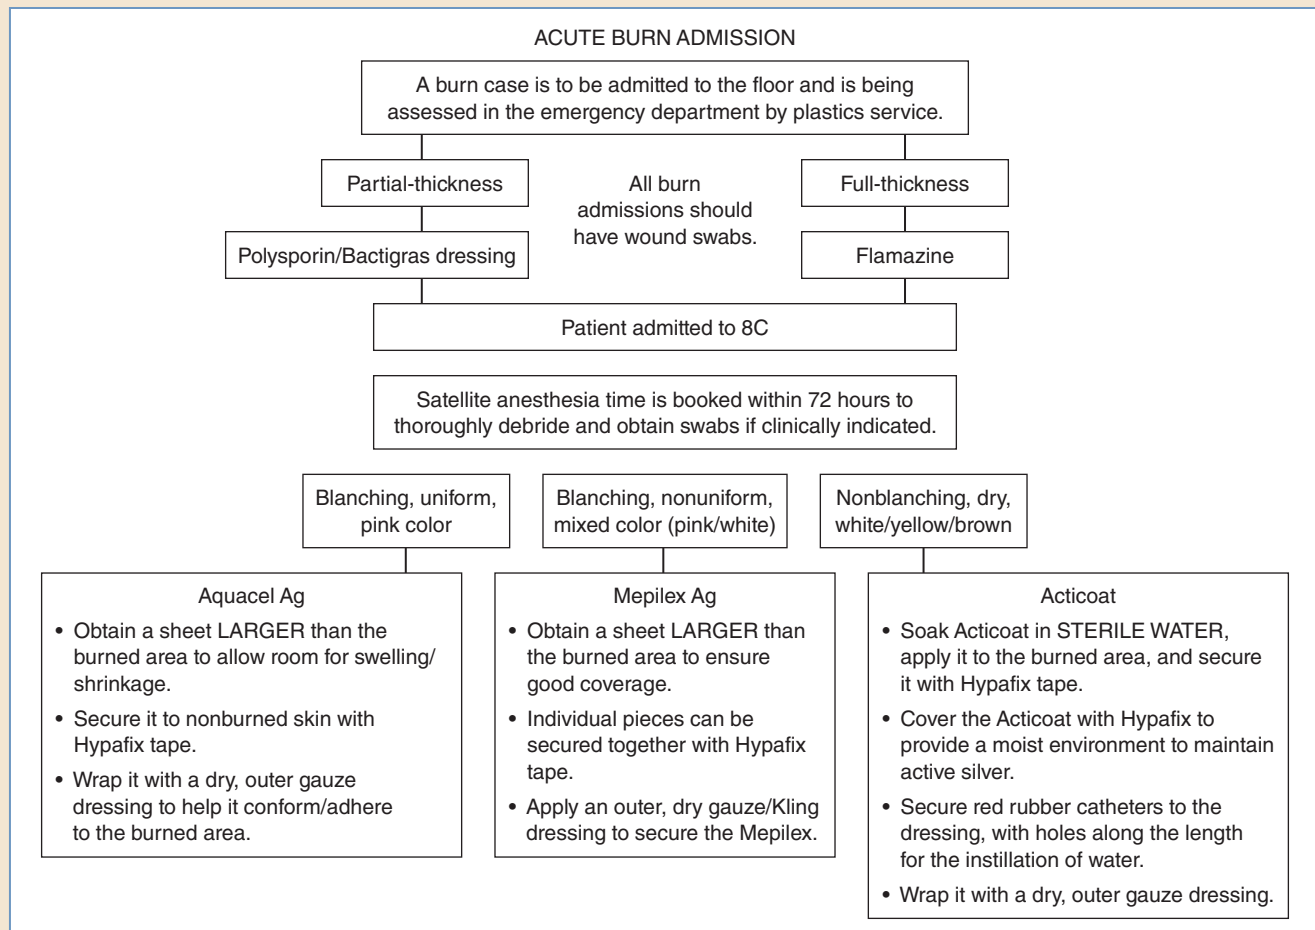

Fig. 9-2 Flow chart for using closed dressings for acute burn patients.

9-1 and 9-2 are guides that help burn care providers choose products.⁵⁵ We have provided our clinical practice guidelines, which present a rationale for product selection and use and can be adapted for any pediatric facility. Appropriate selection and use of long-acting products depends on the burn depth, which cannot be determined until 24 to 72 hours after the injury. Many cases require full sedation/anesthesia for proper application.

Table 9-1 Burn Characteristics and Predicted Healing

Depth	Color	Epithelial Budding	Capillary Refill	Healing	Scarring
Superficial	Red, erythematous	N/A	Brisk, 1-2 sec	N/A	No
Superficial partial	Pink, red	Yes	Brisk, 1-2 sec	Within 7-10 days	No, but may result in a slight color mismatch
Partial	Red, light pink, translucent white	Yes	Sluggish, >2 sec	Usually within 2-3 weeks	Possible if close to 3 weeks
Deep partial	Deep red, white, hemorrhagic staining	No	Sluggish or absent, >2 sec	Longer than 3 weeks, grafting	Yes
Full thickness	Brown, yellow, white, black eschar	No	No	Requires grafting	Yes

Modified from The Hospital for Sick Children (SickKids). Division of Plastic and Reconstructive Surgery, Clinical Practice Guideline, Toronto, Ontario, 2015.

Table 9-2 Burn Depth and Characteristics

Burn Depth	Superficial Partial	Partial	Deep Partial	Full Thickness
Appearance				
Characteristics	Red, cherry pink Blanching Sensate	Light pink, thin white eschar Blanching in areas Sensate Epithelial buds apparent	White eschar, hemorrhagic staining No blanching Sensate/insensate	Leatherlike, yellow, brown, greenish No blanching Insensate
Dressing choices	Polysporin/Bactigras (while awaiting thorough debridement) Aquacel Ag	Polysporin/Bactigras (while awaiting thorough debridement) Mepilex Ag	Mepilex Ag Acticoat	Acticoat SSD (if wound appears infected/symptomatic/presentation is delayed)

Modified from The Hospital for Sick Children (SickKids). Division of Plastic and Reconstructive Surgery, Clinical Practice Guideline, Toronto, Ontario, 2015. SSD, Silver sulfadiazine.

OUTPATIENT MANAGEMENT FOR PEDIATRIC INJURY

Most pediatric burns that occur in developed countries do not require admission to an inpatient unit and can be managed on an outpatient basis. This requires consultation and coordination between the outpatient care providers and the burn care team to ensure optimal results.

Children who do not require fluid resuscitation or supplemental nutrition should be considered for outpatient management. A suitable home situation with parents or caregivers who can support the child through the treatment is imperative. This includes the ability to attend outpatient clinics as necessary.^{56,57}

For successful outpatient management, education of the child (when appropriate) and the parents is vital. This includes how to manage the dressings between dressing changes, what to do if the dressing becomes loose, warning signs that might warrant an early return to the hospital, and the need for ongoing follow-up visits. They should be informed that care will be an ongoing process and may require long-term rehabilitation and follow-up even after the burn is healed.

INFECTION CONSIDERATIONS

Burn wounds are initially sterile but are at risk of bacterial contamination and superimposed infection. Topical antimicrobial dressings are effective in minimizing colonization and reducing the risk of true infection. Prophylactic systemic antibiotics are not warranted, and antibiotic therapy should be reserved for proven infection.^{46,47}

Infections, whether from the wound or other sources, can be difficult to diagnose in pediatric burn patients. The hypermetabolic state causes the baseline temperature to reset at a higher level and frequently leads to tachycardia and tachypnea. Continuous exposure to inflammatory mediators results in significant changes in the white blood cell counts, making these poor indicators of the presence of infection or sepsis. Other signs of infection should be used such as the appearance of the wound, cellulitis, deepening of the burn wound, increasing fluid requirements, and decreasing platelet counts.^{58,59}

If a patient has signs of sepsis, broad-spectrum antibiotics should initially be given while the cause is investigated. Burn wound infection is the most likely cause, and *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the most common causative organisms. Other sources of infection are line contamination, pneumonia, and urinary tract infection. Once a source is identified and cultures have been obtained, antibiotic therapy can be specifically targeted.^{58,59}

Toxic shock syndrome (TSS) is a rare but serious infection that can develop in pediatric burn patients. It is caused by overwhelming infection by toxin-producing bacteria, usually *S. aureus*. Children are uniquely predisposed to TSS. This is thought to be the result of children not having been previously exposed to the toxin and not having developed appropriate antibodies. The mortality rate for children with TSS with a burn is approximately 50%. TSS is not limited to major burns and can occur in children with burns of less than 10% BSA.^{60,61}

ACUTE BURN SURGERY

Acute burn surgery in children has unique aspects compared with that of adults. The principles of surgery are similar, but the practices are different. Families may have difficulty understanding the difference between the burn wound and the burn scar. Discussing this concept with the family is essential, particularly with families of pediatric patients with indeterminate burns in whom the possibility of surgery is low (20%). Most families will have already explored these two entities on the Internet and have various levels of understanding. A multidisciplinary team whose members use the same terminology can help parents to understand that burn wound care and scar care are different, and that they occur at different times. Our approach has been to digitally photograph

all dressing changes and review these with the care providers so they can see the wounds and see how they have changed. This helps to focus the discussion on wound care in the primary acute stages. Spending time early in treatment to clarify this distinction is most helpful for families who suffer the loss, guilt, and traumatic aspects of their child's burn.

The timing of surgery is a major issue in treating pediatric burn injuries. The recent use of laser Doppler technology (Figs. 9-3 and 9-4) has helped to eliminate unnecessary surgery because of its improved accuracy in areas of indeterminate burn depth.^{62,63} Children are more prone to hypertrophic scar formation, and the entire process and purpose of surgery is to provide the best possible outcome of scars. Deep dermal injury increases the probability of hypertrophic scar development⁶⁴; grafting can produce a better outcome. In children, it is challenging to know how long to promote the healing phase and when to perform surgery to ensure an optimal outcome. In some cases, allowing a deep or small, full-thickness injury to heal primarily and treating the scar later is reasonable, particularly when removing the burn and placing donor skin grafts may not give a better cosmetic result. Highly functional areas such as hands are particularly problematic, because small areas of injury can result in dysfunction when not treated early enough.^{65,66}

We favor the use of sheet grafts for all cases of acute surgery until *the size of the donor site is greater than the size of the injury*; mesh grafts are then considered. All meshed grafts heal with the meshed pattern visible,⁶⁷ although those that are not spread can have an excellent cosmetic appearance. Sheet grafts require more care and expertise to apply effectively for excellent results. Each small opening in a meshed graft heals by secondary intention; therefore the scar quality is poorer than that of a sheet graft.⁶⁷ When a sheet graft vascularizes, it does not require healing by secondary intention, and less scar is formed. Sheet grafts should *always* be applied to highly visible areas such as the hands, feet, and face.

The choice of donor site in children requires careful consideration. Scalp grafts for small wounds are an excellent choice, because the donor site is completely hidden once the area heals and the hair regrows.⁶⁸ Often, adjacent skin can be selected for smaller burn injuries in children, minimizing all scarring to one anatomic area. This is useful in the short term, when the surgical dressing is confined to one area, but is more important later, when the scarring and scar therapy, if needed, are similarly limited. We do not favor the use of a buttock graft or a lateral thigh graft, which is often separate from the burn injury area. The use of the diaper region in children increases the nursing requirements for wound care and often makes ambulation and toileting difficult. For moderate-sized burns, we prefer the back as a key donor site (Fig. 9-5, A through C).

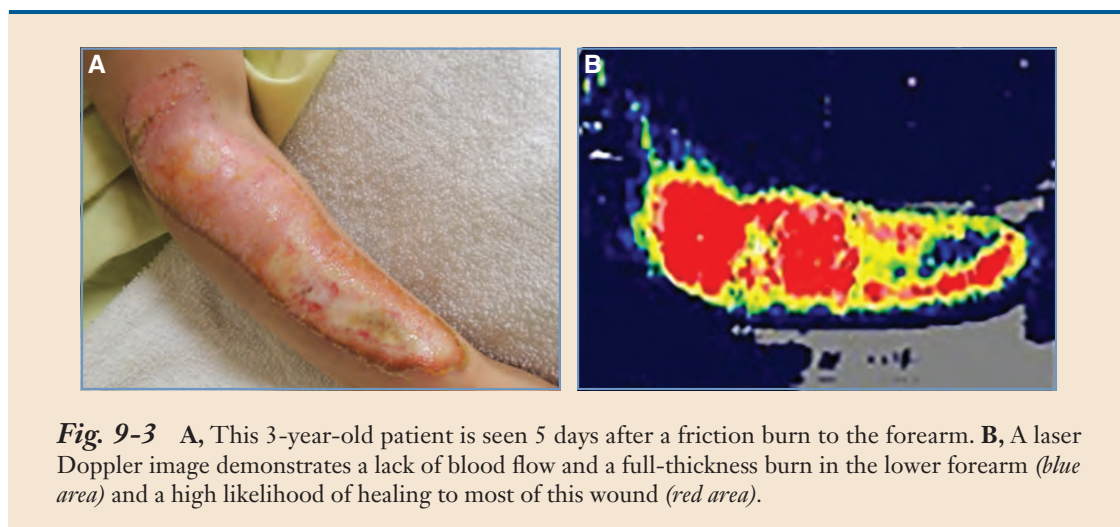

Fig. 9-3 A, This 3-year-old patient is seen 5 days after a friction burn to the forearm. B, A laser Doppler image demonstrates a lack of blood flow and a full-thickness burn in the lower forearm (*blue area*) and a high likelihood of healing to most of this wound (*red area*).

Fig. 9-4 A, This patient has a full facial scald burn and is shown 24 hours after the injury, during debridement and application of a dressing. B, A laser Doppler image indicates a high likelihood of healing to all areas, as evidenced by the *red area*. C, Second-degree burns to the shoulder area. D, A laser Doppler image of the shoulder area.

Fig. 9-5 A, This 2-year-old child had full-thickness scald injuries to the abdomen, shoulder, and arm. Sheet grafts were harvested from the back and used to cover these areas. The donor site was limited to below the scapula and out of the diaper line. B and C, He is shown 6 months after the injury. Early hypopigmentation has developed. The child is receiving laser therapy with pulsed dye and fractional CO₂ laser for severe pruritus and scar modulation.

Large, single sheets of skin are easily harvested, and the dermis, even in a child, is relatively thick, compared with other areas.⁶⁹ The patient position change to prone during the surgery does not add the same amount of time as for an adult because of the patient's small size. The principle that may need to be applied for choosing a donor site in children with a burn injury is to select, where possible, the skin that will eventually resemble most closely the area treated, which is often the adjacent regional skin.

Intraoperative hypothermia is a consideration in all burn surgeries, but young children are more susceptible than adults, particularly when large areas are burned. An operating room that has isolated and self-controlled heat to allow the environment to be warmed is an absolute necessity.⁷⁰ Underbody and overbody warmers play a role,⁷⁰ especially for patients with smaller burn injuries. However, larger burns require exposure of large areas of the body surface, and surgery is not possible unless the patients are adequately warmed. Some patients have been successfully treated with staging to minimize heat loss, especially those younger than 2 years of age. In the first stage, the lower extremities and pelvis are exposed and operated on, while the upper half is warmed. Dressings are applied. In a separate stage, surgery is performed on the upper half of the body.

The infiltration of subcutaneous tumescent solution is another essential step in safe acute pediatric burn surgery. Vasoconstriction with dilute adrenaline or phenylephrine minimizes blood loss during the donor-site harvest, and the tumescence of the tissues helps to ensure an even and consistent graft harvest.⁷¹⁻⁷³ The maximum dose of subcutaneous fluid that can be infiltrated is not known, although children are able to absorb fluid from the interstitium. However, once the fluid is infiltrated and the donor site harvested, the fluid has a natural exit point directly through the harvested skin bed; therefore the amount of infiltrate is not typically counted as part of the intravenous resuscitation. This technique requires the use of bulky absorbent dressings for the donor site and a well-adherent dressing that allows clotting when the effects of the vasoconstrictor wear off. Tumescence is a safe practice. It is inexpensive and transportable to third world countries where rates of anemia from infectious and dietary reasons are common, and blood products are not easily available. Effective topical application of an adrenaline-soaked sponge directly onto open granulation tissue before excision, without direct injection, has been reported.^{72,73}

SPECIALIZED TREATMENT AREAS

Palm Burns

Contact burns of the palm are common in young children because of their interest in exploring their environment. Most (approximately 80%) of these heal without requiring surgical intervention.^{74,75} However, burns that will require surgery need to be identified as early as possible to provide surgery and therapy in a timely fashion, with the goal of minimizing the resultant functional deficit.

Surgery on palm burns involves debridement with tourniquet control. The wound is best resurfaced with a full-thickness skin graft, which will reduce scar contraction.⁷⁶ The grafts are dressed and the hand splinted in a functional position. Where possible, the uninjured fingers should remain out of the dressing to encourage movement.

The splint is removed and the dressing debulked as soon as the graft or grafts are stable enough to tolerate movement. Young children will naturally start using their hand as comfort allows and will perform their own hand therapy; older children should begin more formal hand therapy.

Despite the best care, hypertrophic scarring and flexion contractures will develop in some cases. Aggressive scar management and hand therapy are essential. Further reconstructive surgery is commonly required as these children age and grow.⁷⁴⁻⁷⁶ The challenges of rehabilitation after surgical reconstruction for volar burns requires the specific knowledge and skill of specialized burn therapists with experience. Close observation of these children through adolescence is needed to ensure the scars do not create secondary deformity.

Breast Burns in Young Females

Burns to the anterior chest of a prepubescent female can damage the skin overlying the breast bud or the breast bud itself. Burns severe enough to require surgery should be approached in the same manner as any other skin burn. However, specific considerations are needed.

Where possible, the nipple-areola complex should be managed conservatively and complete removal of the nipple avoided. The absence of a nipple is a very noticeable deformity and can be very distressing for young girls.⁷⁷ When burns to the breast skin are debrided, the underlying breast bud should not be damaged.⁷⁷⁻⁷⁹ Any damage to the breast bud, whether iatrogenic or caused by the burn itself, will affect breast development. The burn wound should be resurfaced with a full-thickness graft where possible or a split-thickness sheet graft.

As a patient reaches puberty, the skin graft and/or burn scar might restrict breast development in this region and result in a constricted breast-type deformity.⁷⁷⁻⁷⁹ Patients should be informed that because symmetry can be affected, they may require further surgery once they have fully developed.⁷⁷ This area is a common area of injury with scald burns. The timing of reconstruction is controversial. Surgeons need to balance the needs of the adolescent female with the ability to provide a reconstruction that will last through the growth phase into early adulthood. Early referral to a breast reconstruction unit well in advance of the need for surgery is often helpful for patients who have breast scars after a thermal injury. It assists families and patients in preparing for possible future surgeries.

PEDIATRIC OUTCOMES

Patients 5 to 20 years of age have the most favorable survival outcomes from burns. Younger patients, especially infants, have higher rates of morbidity and mortality.^{5,11} As with all age groups, a larger burn extent and/or a deeper burn correlates with a poorer prognosis. Burns from house fires are among the leading causes of burn-related deaths in children. Scald burns are rarely associated with mortality.^{11,80}

There have been significant improvements in morbidity and mortality from pediatric burns over the past few decades. Advances in fluid resuscitation, wound care, infection control, nutritional support, and early surgical management (where necessary) have contributed to a significant decline in burn-related hospital admissions and deaths in children.⁸⁰⁻⁸²

The psychological impact of burns on children should not be underestimated. Children have to adjust to society's impression of their injury, especially when scars are visible. However, previous studies from the Shriners Burns Institutes show that most pediatric patients with burn injuries appear to be satisfied with their overall quality of life.⁸³⁻⁸⁶ This is especially true for children with supportive families.⁸⁷ A study published from the Netherlands in 2013 showed that although some children had long-term psychological problems such as anxiety, depression, and difficulties with social functioning, there was little evidence that behavior in general, self-esteem, or body image were impaired in the total population of children with a history of burns.⁸⁸

KEY POINTS

- Pediatric burns are common and largely preventable.
- Children who weigh less than 30 kg require maintenance fluid in addition to resuscitation fluid.
- Hyponatremia is the most common electrolyte abnormality in pediatric burns.
- Pain control is paramount for obtaining a favorable outcome.
- The closed technique for dressing changes has had a positive impact in the pediatric population.
- Use of scanning technology is helpful for assessing burn depth in scalds.
- Sheet grafts should be used wherever possible.
- Education of the child and family throughout the process will facilitate treatment and minimize the negative psychological impact.

Pediatric Burn Reconstruction

Mirko S. Gilardino • Jugpal S. Arneja • Jonathan Kanevsky

he principles of burn reconstruction in pediatric patients include (1) restoration of injured areas to as close to normal as possible for psychological and emotional rehabilitation, (2) optimization of the patient's ability to resume activities as close to preinjury level as possible, and (3) reestablishment of the natural aesthetic appearance of the child. The management of pediatric burns has changed over the years to one of early excision and coverage.¹

BURN INJURIES IN CHILDREN

Epidemiology

Of the more than 1 million major burn injuries in the United States each year, approximately half occur in children.² Although the incidence of burn injury is decreasing, these injuries still account for more than 30,000 hospital admissions and as many as 5000 pediatric deaths yearly. Burn injuries are a significant cost to society in terms of acute management, rehabilitation, and long-term care, with costs totaling \$80 billion per year.

Compared with burns in adults, flame burn injuries are associated with a relatively higher morbidity and mortality in the pediatric population. Another special issue in childhood burn injury is that although 80% of the injuries are related to accidents, up to 20% are thought to be the result of neglect or abuse.

Etiologic Factors

The most vulnerable pediatric age group susceptible to burn injury is children younger than 5 years of age. Scald, contact, and electrical injuries are most common among children. Scald injuries are more common in children younger than 4 years of age and generally involve less than 20% of the total body surface area.³ These typically result from bath water in unsupervised situations. The depth of scald injury depends on the temperature of the water, the child's skin thickness, and the duration of contact. Water at 60° C (140° F) causes a deep dermal burn in 3 seconds, whereas water at 69° C (156° F) will cause the same depth of injury in 1 second.³ Patients with scald injuries classically present with mixed burn depths. Another common scenario for scald burns is when toddlers pull containers of hot liquid from counters and tables. This produces a classic pattern of burns to one side of the scalp and face, with scalding extending down the arm to the chest.

Most massive burn injuries (that is, greater than 40% of the total body surface area) occur in school-aged children and adolescents and are commonly caused by flame burns.⁴ House fires are the most common cause of flame burns. Other sources include candles, fireworks, and campfires. The leading cause of mortality in pediatric burns is house fires, with a third of these injuries associated with cigarette smoking. Fires in enclosed areas also cause inhalation injuries, which, combined with associated direct thermal injuries, contribute significantly to morbidity and mortality. The incidence of major burn injuries has decreased over the past 10 years as a result of greater education and awareness about fire prevention.

Electrical injuries most commonly occur when children bite electrical cords or place metallic objects in an electrical outlet. The injury is usually a combination of both thermal injury from the associated flash (electrical spark) and direct injury from the current running through tissue. Older children are subject to high-voltage injuries from contact with transformers and high-tension lines.

Contact burns are fairly common, with irons and hair curlers being the most common sources. Oven doors, space heaters, and the glass fronts of gas fireplaces are frequent causes, especially for palmar burns. Hot mufflers from motorbikes, cars, and motorized equipment, especially when associated with vehicular accidents, can cause significant deep injuries.

Chemical burns can occur by contact or ingestion. The most common agents are lye-based drain cleaners, but injuries can occur from bleaches and acid cleaners.

Because an estimated 20% of pediatric burns result from abuse or neglect, physicians should suspect the possibility of abuse if hallmark patterns of injury are present or if eliciting a history from the parent or guardian is difficult. Intentional burns such as “dipping” burns, in which a child is dipped into hot water, produce a typical pattern of burns to the buttocks, perineum, and feet, with sparing of the flexion creases because of defensive posturing. Cigarette burns leave a circular, punched-out pattern. Other clues include a history of repeated trauma, blaming a child or sibling for the burn, or the burn occurring when the child is in the care of someone other than a parent.

Scarring

Unlike the process of adult scar maturation, children often undergo a more significant and lengthier inflammatory phase of wound healing. This process is followed by an exaggerated maturation phase. The entire cycle may take 12 to 18 months for the scar itself to mature. However, the fourth dimension of scar maturation is related to patient growth, which can affect scarring, because scar tissue can limit growth and produce contractures.⁵ The goal after a burn injury is a

soft, stable, pliable, avascular scar with normal pigmentation. Several preventive efforts can assist in achieving this result.

Risk Factors

The potential for hypertrophic or keloid scarring is largely unpredictable; however, there are many risk factors for abnormal scarring in a burn injury. All of the following influence the potential for abnormal scarring: the mechanism of injury (burn type), the length of time for a burn wound to heal (more than 14 to 21 days), the anatomic location (surrounding a joint, the chest, or the back), ethnicity (Asian and black patients are more likely to develop hypertrophic or keloid scarring than other ethnicities), and patient age (growing children may develop contractures, and teenage children may exhibit lengthy inflammatory scarring).⁶

Preventive Efforts

Prevention of abnormal scarring begins in the acute care setting immediately after a burn injury.⁴ Early recognition of burns that will heal spontaneously versus those that will require lengthy periods (more than 21 days) to reepithelialize is essential to minimize hypertrophic scarring. Predicting which burns will heal spontaneously often is determined by the mechanism of injury. Fortunately, most pediatric burns are scalds and should heal with meticulous wound care, good nutrition, and prevention of infection. If a scald burn does not heal by 21 days, tangential excision and grafting should be considered. Flame contact burns rarely heal spontaneously and should be rapidly excised and grafted.

MINIMALLY INVASIVE TREATMENT MODALITIES

After a burn wound is healed, either as a result of surgical excision and grafting or by spontaneous healing, the risk of abnormal scarring persists at the donor site and recipient site. In adult patients, grafting alone is usually sufficient without the need for aggressive postoperative adjuvant treatment. This is not the case in pediatric patients because of a constant dichotomy between scar hypertrophy and contraction in opposition to growing children, who may exhibit inflammatory wound healing.⁶

Pressure and Scar Massage

The use of pressure is the most reliable and proven modality for preventing or treating abnormal burn scars.⁷ This therapy can be augmented with a physical and occupational therapy program consisting of range of motion, stretching, splinting, and massage. This scar care continuum actively attempts to reduce hypertrophy and contracture and to prevent the need for reconstruction.⁸⁻¹⁰ To be effective, pressure on the scarred regions must be consistent, with garments worn for most of the day. Pressure garments must be worn in this manner until the burn scar is fully matured. Silicone gel sheets or inserts have also shown additional benefit.¹¹ Pressure garments can be customized to all areas of the body and will need to be routinely reevaluated as the child outgrows these garments. Masks should be considered for facial burn scarring (Fig. 10-1). Burns across joint surfaces should be managed with garments and splints (Fig. 10-2). Applying pressure to the wound is an integral part of care and must be reintroduced whenever a reconstruction requires a skin graft.

Scar massage with a lotion, cream, or oil adds moisture (sweat and sebaceous gland function may be poor after a burn injury) and increases blood flow to the scar, which may assist in a more rapid scar remodeling process.⁷

Fig. 10-1 Examples of garments and masks. **A**, Typical Uvex masks cast directly or generated by laser surface scanning. **B**, Facial Spandex mask. **C**, A Spandex bra may be used with silicone inserts. (Courtesy of Shriners Hospital for Children–Cincinnati Unit.)

Fig. 10-2 Lightweight hand splint placing the hand in a safe position.

Corticosteroid Treatment

An additional measure for managing a hypertrophic scar before beginning an aggressive surgical reconstructive program is the use of an injectable corticosteroid. For an established burn scar, triamcinolone (Kenalog, 40 mg/ml) injected intralesionally every 2 or 3 months has shown evidence of improving hypertrophic and keloid scarring.⁶ The goal of this therapy is to turn off the prolonged inflammatory phase of wound healing that increases collagen deposition and scar hypertrophy. Risks associated with this treatment are thinning of the dermis and pigmentary changes.

Laser Treatment

Persistently erythematous burn scars with or without hypertrophy may also respond to laser treatment. The 585 or 595 nm pulsed dye laser, with a target chromophore of oxyhemoglobin, has been shown to manage the persistent vascularity associated with scarring.¹² Hypertrophy associated with the scar can be reduced with the pulsed dye laser, using the laser alone or in conjunction with intralesional corticosteroid.¹³

For scar hypertrophy, stiffness, and abnormal textural change, the CO₂ laser has been used with some success. The 10,600 nm CO₂ ablative laser has been reported to improve small regions of undulation and irregularity by producing a controlled epidermal/partial-thickness dermal injury that spontaneously heals.^{12,13}

RECONSTRUCTION BY ANATOMIC AREA

Improved survival from major burns has led to increased and more complex secondary burn deformities that can significantly affect aesthetics and function. A loss or obliteration of anatomic features and structures can occur as a direct result of a burn (such as loss of an ear helix, nasal tip, or finger) or problematic scarring, resulting in restricted motion and/or growth. Despite appropriate wound care, pressure dressings, splinting and physiotherapy, troublesome burn scars can arise rapidly within the first few months after an injury.

If the tissue available for autograft is insufficient, intermediate tissue substrates can be used. Integra is an example of a bilayered, collagen-based dermal regeneration template. In children it is used with favorable outcomes in acute burn care and burn scar revisions.¹⁴ Integra is just one of many different kinds of dermal regeneration templates available.

Growth, development, and inconsistent patient cooperation should be routinely considered when planning the reconstructive needs of a burned child. Reconstruction generally takes place after scar maturation is complete. Two areas may require earlier intervention in burned children: the neck and eyelids.³ Because of significant restriction in range of motion, neck contractures can complicate general anesthesia by causing airway access issues; thus they require prompt attention. Contractures of the eyelids can cause exposure keratitis and corneal ulceration. Timely reconstruction is needed to prevent loss of vision.

Head and Neck

Cosmetic deformities in the face are generally combined with functional concerns, given the importance of facial expression and appearance in everyday social interactions. Furthermore, it is challenging to camouflage burn scars on the head and neck with clothing or coverings. The components of the head and neck that are to be considered when planning a reconstruction are the face (eyelids, eyebrows, mouth, ears, nose, and jaws), scalp, and neck. Definitive reconstruction of the burned head and neck should be postponed until skeletal maturity.

Fig. 10-3 Release and resurfacing of the lower lip with an expanded neck flap. **A**, Preoperative extensive scarring of the chin. **B** and **C**, Postoperative resurfacing with expanded neck skin. This patient also required a bilateral sagittally split mandibular advancement.

Face

The approach to resurfacing should follow the unit and subunit approach of facial aesthetics first described by González-Ulloa in 1956.¹⁵ The goals of treatment are the following¹⁶:

- A face that is normal at a conversational distance
- Maintained facial balance and symmetry
- Distinct aesthetic units fused by inconspicuous scars
- A doughy skin texture appropriate for corrective makeup
- Dynamic facial expression

Consideration of the location and direction of the borders of skin grafts is essential to ensure that scars are concealed along natural skin tension lines and anatomic borders. The areas most likely to cause secondary functional deficit are the skin surrounding the eyes, nose, lips, and mouth rather than the cheeks or large, flat areas. Appropriately placed Z-plasties can prevent scar band formation between the aesthetic facial subunits. To minimize scarring, mesh grafts should not be used in the face, and full-thickness grafts should be used whenever possible.

Sheet grafts, either full- or split-thickness, are preferred for resurfacing. Given the contours of the face and difficulties using bolster dressings, vigilant daily aspiration of any collections under the grafts is required. If the neck is spared, the surgeon can expand the neck skin to advance to the face (Fig. 10-3), but this may cause additional problems by placing tension on the mouth and eyelids. Large cervicofacial flaps can also be used.

Eyelids

Eyelid contractures, primarily of the lower lid, can lead to ectropion and corneal exposure.¹⁷ Although tarsorrhaphy can be a temporary solution, its use should be limited to the acute care

Fig. 10-4 Lower eyelid release with a graft. **A**, Preoperative lid retraction. **B**, Postoperative result.

Fig. 10-5 Upper lid contracture. **A**, Preoperative contracture. **B**, Postoperative result.

phase, and the lid should be reconstructed or resurfaced as soon as possible.¹⁸ Ectropion may be either intrinsic or extrinsic. With intrinsic contracture, the ectropion is caused by scarring and shortening of the lower lid itself. In extrinsic contracture, scarring of local tissues in the cheek or neck is responsible, despite an uninjured lower eyelid. Extrinsic contractures can also occur from reconstructive efforts, such as local tissue transposition or expansion that leads to unintentional pull on the lower lid. The initial treatment should be release of the primary site of contracture, whether it is the lid itself or a distant site. This usually corrects the ectropion. If adequate lid release is not obtained by releasing the extrinsic contracture, full-thickness grafting of the eyelid is frequently necessary.

If upper eyelid skin is inadequate or unavailable because tissue has been burned, other favorable donor sites include retroauricular skin or the inner upper arm (Fig. 10-4). Occasionally, a laterally based unipedicled Tripier flap with a canthopexy will elevate the lateral canthus and release and reposition the lower lid. If middle lamellar damage occurs, support for the lower eyelid can be improved with conchal cartilage or deepithelialized hard palate mucosa.

Upper lid retraction and resultant lagophthalmos is a less common cause of corneal exposure. Treatment is similar to that of ectropion, involving release of the contracture with inlay grafts (Fig. 10-5). If both eyelids are involved, the best results are obtained by staging the releases.

Entropion can also occur from a burn injury, but it is less common than ectropion. The pathophysiology differs from that of the typical congenital involutional or cicatricial forms seen in nonburned individuals. Patients with entropion typically have a normal underlying lamella, but the lid is rolled in by transverse shortening caused by scar contracture. This is corrected by releasing the transverse bands, usually with grafting. This allows the lid to lengthen and redrape. If this fails and the lid is of normal transverse length, a typical tarsal procedure may also be necessary.

The total loss of eyelids is fortunately rare, but if it occurs, the destruction of surrounding structures usually precludes local flap reconstruction, and a free tissue flap must be considered.¹⁹ The surgeon should take into account drainage, lubrication, and an opening for sight.

Eyebrows

Reconstruction of the eyebrows depends on the extent of the loss, the condition of the underlying tissues, and the wishes of the patient.^{20,21} Tattooing can offer aesthetic improvement, particularly in less favorable scar beds. If the bed is adequate with good vascularity, micrografts can be attempted. For more extensive loss, free strip grafts harvested from the occipital or parietal scalp can be used (Fig. 10-6). These grafts should be less than 1 cm wide, because vascular ingrowth occurs initially from the recipient site margins, not the base. Care should be taken to orient the strip graft to mimic the normal direction of hair growth. In the most severe cases with loss of supporting tissue, reconstruction can be accomplished with pedicled vascularized strip grafts based on the temporal artery²² (Fig. 10-7).

Fig. 10-6 Scalp strip graft reconstruction of an eyebrow. **A**, Total loss of right eyebrow, seen pre-operatively. **B**, Immediately after the strip graft. **C**, Long-term result. Hair growth is best along the periphery of the graft. (Courtesy of Shriners Hospital for Children–Cincinnati Unit.)

Fig. 10-8 Staged unit release of the upper and lower lip. **A**, Preoperative lower lip ectropion. **B**, Following unit release of the lower lip. **C**, The lip healed before the upper lip unit release was performed. **D**, Following upper lip release. **E**, Long-term result.

Mouth

Reconstruction of the mouth should be separated into the lower and upper lip if reconstruction of both is required (Fig. 10-8). A common problem in the upper lip is thinning or loss of the philtral dimple (Fig. 10-9), which is difficult if not impossible to correct. In the lower lip the pull of the scar often dramatically lengthens the lip transversely. It is often helpful to shorten this distance with a midline vertical wedge resection at the time of unit release. This allows the lip to rise and restores oral competence. Tight commissures will usually persist after release of the lips and will have to be addressed separately. They can be released with either separate inlay skin grafts

Fig. 10-9 Darting a unit release of the upper lip. **A**, Preoperative retraction of the lip and nose. **B**, Immediately following release (with extension across the nasolabial folds). **C**, Long-term result. The lip is elongated and thin, with loss of the philtral dimple.

or mucosal advancement flaps. Perioral banding from circumferential oral burns causes special problems by restricting the opening, restricting chin and mandibular growth, creating lip ectropion, and creating malocclusion from pressure on the teeth (Fig. 10-10; see Fig. 10-9). Commisuroplasty can be performed to restore the features of a normal mouth with a musculomucosal advancement flap in Y-to-V fashion.

Ears

Reconstruction of a burned ear is challenging because of scarring that prevents facile redraping of local skin over new cartilage frameworks. Burns commonly destroy the helix and leave the conchal bowl intact. The thickened surrounding skin may be delayed and rolled to create an acceptable helix. For more extensive loss, a typical cartilage framework can be carved from rib and covered with a temporoparietal flap and split-thickness skin graft (Fig. 10-11). In the most severe burns, prosthetic ears can be used with bone anchors if needed.²³

Nose

Nasal reconstruction is one of the most important elements in rehabilitation for patients with devastating deformities of full-thickness facial burns. The burned nose is a prominent feature of the face that presents reconstructive challenges, including total or partial loss, obliteration of features, and stricture of the airway. When possible, we use a single pedicle for complete nasal

Fig. 10-11 Reconstruction of ear with temporoparietal flap. **A**, Burned ear defect. **B**, Raising the temporoparietal flap. **C**, Rib cartilage graft. **D**, Rib graft covered with a flap and a split-thickness skin graft. **E**, Final result.

reconstruction. The forehead generally furnishes the best donor area. More distant donor sites are used if the forehead is not available. In lesser deformities, resurfacing with composite grafts or full-thickness skin grafts gives satisfactory results. Nasal reconstruction in children should be staged, with the nasal dorsum contracture addressed in the first stage and the final correction performed in the second stage once the face is mature. Scars and grafts in the area of the nasal dorsum and glabella produce contractures that result in flattening and widening of the nasofrontal angle. Modified Z-plasties can be used to correct the nasofrontal deformity.

Nasal burns also cause retraction of the nares and obliteration of the alar bases. Frequently, this can be improved with simple unit resurfacing, turning the margins of the nares down to correct the retraction. Obliteration of the alar bases is very common and difficult to correct. Improvements can be made by releasing the base and placing a small full-thickness graft below the alar base to re-create the natural curve. For total or partial loss of the nasal structures, surgeons must borrow from experience with skin cancer patients. Lining, cartilage support, and covering must be supplied. Ideally, the forehead is the perfect donor site, but with burns severe enough to result in nasal loss, the forehead is rarely spared.²⁴ If it is available, however, it should be used. Free flaps, typically radial forearm, can be used for total nasal reconstruction in conjunction with

Fig. 10-12 Total nasal loss reconstructed with a free radial forearm flap. **A**, Initial defect. **B** and **C**, Postoperative reconstruction with turn-down flaps for lining, rib grafts for skeletal support, and a free radial forearm flap for coverage. (Courtesy of Shriners Hospital for Children–Cincinnati Unit.)

rib grafts to provide both bony and cartilaginous support (Fig. 10-12). Limitations of donor sites may also necessitate the use of a classic Tagliacozzi nasal reconstruction or distant tubed pedicled flaps brought up on wrist carriers.

Nasal stricture caused by collapse and hypertrophic scarring can be released and treated with full-thickness inlay grafts followed by prolonged splinting.²⁵ If an unburned ear is available, a composite chondrocutaneous graft harvested from the anterior surface of the triangular fossa provides a useful inlay graft with minimal subsequent contraction.

Jaws

The forces generated by burn scars and the associated treatment, including pressure garments and masks, often can have a profound effect on growth and development of the maxillofacial skeleton. The forces of scars on the facial skeleton can lead to malocclusion and retrusion of the mandible. Correction involves release of the deforming force, whether it is a scar or a mask.²⁴ Typically in the lower face, pressure from a burn scar or mask will initially result in loss of chin prominence. If the force is persistent and sufficient, it will eventually change the occlusion to Angle class II. Constriction from facial burns can also restrict growth and alter the direction of maxillary growth, resulting in class III occlusion and/or open bites (Fig. 10-13). In all cases, the restricting forces should be released and orthognathic surgery performed as necessary to correct the deformity. Overcorrection with osseous genioplasty is an established approach for managing a postburn retrusive chin.²⁶

Scalp

Until the introduction of tissue expansion, scalp reconstruction was limited to staged excision of alopecia, a Juri flap^{27,28} transposed to create a hairline, and Orticochea flaps to redistribute the remaining hair in a single stage.²⁹ The unique nature of the hair-bearing scalp precluded distant flap or graft reconstruction. Tissue expansion has basically eliminated the need for most local flap procedures.³⁰ Tissue expansion is well tolerated, can be repeated multiple times, and replaces like with like tissue. Serial expansions can be used to reconstruct losses of up to 50%

Fig. 10-13 A difficult case of an adolescent male who fell into a cooking fire as a young child. His chin was scarred to his chest and resulted in elongation of his mandible, retraction of his maxilla, a 34 mm occlusal underjet, and severe neck and facial scarring. **A** and **B**, Following extensive neck release. **C**, An intraoperative bilateral modified Weber-Ferguson approach to the maxilla was necessary because of severe scarring and contracture. **D-E**, Soft tissue release and resurfacing were necessary after a LeFort I advancement of 17 mm and a sagittal split mandibular setback of 17 mm. **G** and **H**, Final result. (Courtesy of Shriners Hospital for Children–Cincinnati Unit.)

or more of the hair-bearing scalp. Factors to consider are the quality of the remaining scalp, the hair density, and the state of the burned scalp. Expansion does not create new hair follicles; it only spreads out remaining follicles. For example, thin blond hair may appear sparse after several expansions. Spotty burns can be difficult to reconstruct, making large expansions difficult. The condition of the burned scalp is also a major factor. Skin-grafted, partial-thickness loss and a grafted galea are usually stable. Skin-grafted periosteum or grafts on decorticated bone can be unstable and prone to breakdown. Although expanded scalp is ideal for covering these unstable areas, the lack of suitable donor scalp may require free flap reconstruction such as a latissimus dorsi flap with skin grafting.

Tissue expansion involves placing one or more expanders around the area of alopecia (Fig. 10-14). Ideally when planning, surgeons should take into account the available unburned scalp, the direction of the hair growth, the possibility of future male pattern baldness, and the density of hair growth. In severe loss, this may not be possible. In general, the largest possible expander should be placed adjacent to the area of alopecia. Textured expanders and expanders with backing should not be used. The complication rate in children is high; complications include infection, exposure, and leaking.^{31,32} To reduce complications it is helpful to let the wound heal fully (about 3 weeks) before beginning expansion. The incision for the insertion should also be carefully planned. It should be in healthy, thick, well-vascularized tissue. Typically it is placed along the margin between the burned and unburned scalp. Scalps can be reexpanded multiple times.³³ If the first expansion does not provide sufficient coverage, a tissue expander can be reinserted at the time of removal and the first attempted advancement. This, however, carries a much higher complication rate, and most surgeons prefer to allow the wound to heal and stabilize before starting another expansion of the same area.

Trunk and Breasts

Burns to the trunk in children are generally from ascending flame burns from clothing or descending hot fluid pulled from above. Boys and girls have negative cosmetic effects from disfigurement of the trunk. Scar band contracture of the trunk is usually less of an issue than when it occurs on extremities, because the range of motion is greater with extremities. Symptomatic bands typically occur along the flanks and across the back between the shoulders. The bands often tighten during growth spurts, although mere tightness is not always an indication for release. The bands may stretch, but they do so at a slower rate than unburned skin. Surgeons should wait about 6 months to determine whether they relax on their own. The bands are released in standard fashion with inlay grafts or local flaps.

Reconstructive surgeons must consider an additional psychological stressor in girls: the loss of femininity for the developing female with a deformed breast. During the acute treatment phase, excision of severely burned tissue is necessary. Aggressive debridement is associated with a higher incidence of loss of breast tissue. Allowing the eschar to fully demarcate before tangential excision optimizes the debridement. Many surgeons suggest that debridement should be done conservatively or not at all within 2 to 3 cm of the areola, because the entire breast will arise from the breast bud beneath the nipple-areola complex (NAC).

After the initial debridement and coverage with split-thickness skin grafts, patients will either develop a normal breast that may be hindered by scar contracture or have deficient breast development from extensive debridement or burn injury. The reconstructive pathway is usually initiated with release of scar tissue in the area of the breast. Most patients undergo surgery during the younger teenage years.³⁴ Release surgery can be performed when breast tissue bulges through unburned areas, but timing is greatly based on the surgeon's best judgment.

Fig 10-14 A, This 9-year-old boy had a flame contact burn as a toddler that developed preauricular and postauricular hypertrophic scarring. B, Placement of a cheek tissue expander (filled midway). C and D, The expander was completely filled. E and F, The tissue expander was removed, the burn scar excised, and the flap advanced. G and H, He is shown after reconstruction.

Fig. 10-15 An unusual case of bilateral burned breasts complicated by tubular breast deformity. **A**, Preoperative burn and congenital deformities. **B**, Following extensive release and resurfacing of the breasts, showing the extent of the congenital deformity. **C** and **D**, Following secondary correction of the congenital tubular deformity.

The locations of scar releases are typically in the inframammary crease, between the breasts, and around the areola. Postoperatively the grafts are placed in compression garments with silicone inserts to apply appropriate pressure to the graft sites. Ideally, the constricting envelope is released when the breast is fully developed (Fig. 10-15). In severe situations release may be required early and may have to be repeated. Release can also be combined with resurfacing if needed and if skin is available.

Most female patients with burn injury to the breasts will undergo the inframammary releasing procedure in their early teens. However, for those requiring greater reconstructive needs, it is wise to wait until the patient is in her early twenties. This allows full, natural breast development. Once full breast development is complete, several options are available for augmenting the breast tissue that is present.

Breast reconstruction options include autologous and implant-based reconstruction or a combination of the two. The size of the remaining breast, the elasticity of the chest wall and overlying skin, and donor site availability must be evaluated. The skin is often thin and friable much like irradiated skin. Therefore the risk of expander erosion, skin necrosis, and infection is higher than in normal skin. If the grafted skin is of good quality and texture, expanders should be placed in the submuscular position.

A flap is usually necessary in situations in which the skin graft has been placed on the ribs with minimal pectoralis muscle present. The most commonly used flaps are the latissimus dorsi flap and the transverse rectus abdominis myocutaneous (TRAM) flap. The latissimus dorsi flap provides a natural breast mound that is a reliable bed for NAC reconstruction. Although the TRAM

Fig. 10-16 Simultaneous nipple-areolar release and reconstruction with breast mound release. **A**, Immediately after release and nipple reconstruction with a skate flap. **B**, Scar control with a Uvex bra. **C**, Final result.

flap is a viable option for postmastectomy patients, it may pose challenges in pediatric patients, because they have insufficient abdominal laxity (especially if nulliparous), and they may not have enough tissue for viable breast reconstruction. Furthermore, patients with burns to the breasts often also have burns in the abdominal area, limiting the use of the TRAM flap.

Regardless of the reconstructive approach, patients will require NAC reconstruction of the affected breast and probably a balancing procedure if the contralateral breast is unaffected. The NAC can be reconstructed with the inframammary release if the nipple-areolar position is easily ascertained, but in some cases a periareolar release is also necessary (Fig. 10-16). Any remnant of the patient's own nipple or areola should be used and reconstructed. In general, with a total loss of the NAC, the reconstructed complex should be placed in the ideal aesthetic site once the breast mound is fully released. Because of scar contracture, burned breasts are less likely to develop ptosis. If a patient can feel a nipple sensation when the nipple is not apparent on gross examination, the nipple-areolar reconstruction should be centered around this site. Nipple-areolar reconstruction techniques are similar to those used in breast cancer reconstruction. Grafts and tattooing are used for areolar reconstruction, and local flaps are used for nipple reconstruction (bell, modified star, and skate flaps). Skate and star techniques are reported to have the best long-term projection.³⁵

Future pregnancy is an additional concern for young girls with burns to the trunk. However, the constricting abdominal scar is not associated with an increased risk of complication, compared with the unburned population. Two large series, one from the Houston Shriners Unit³⁶ and one from the Cincinnati Shriners Unit,³⁷ investigated this issue. Both series studied the effects of large burns (greater than 50% of the total body surface area) and circumferential burns on childbearing. Despite differential expansion of the abdomen caused by the presence of burned

and unburned areas, the patients mirrored the unburned population in complications, the incidence of vaginal versus C-section delivery, and the ability to carry. There have been scattered reports of a need for surgical release of the expanding abdomen and postpartum release, taking advantage of the stretched unburned skin. Pregnancy in healed burned patients usually does not require any subsequent intervention.

Hands

As with facial burns, reconstruction of hand burns starts during the acute care period. Proper management at this stage reduces the need for later reconstruction and enhances functionality. Hand burn injuries should be kept elevated above the heart, rapidly debrided, and resurfaced. The hand should be placed in a safe position. Although pinning joints may be necessary, pins should be removed early, and an aggressive splinting and exercise program should be instituted. Hands should be resurfaced with sheet grafts wherever possible, especially if they do not heal within 14 days. The close proximity of vital structures (that is, joints and tendons) to the surface of the skin increases the likelihood of damage to these structures and a subsequent need for acute or early flap reconstruction. Early mobilization of the joints in a burned hand ensures the best chances for restoration of function.

McCauley³⁸ has studied and classified the correlation between the extent of burn injury to the hand and functional outcome. Category I injuries required no surgical intervention in the management of superficial partial-thickness burns; almost all (97%) of these patients had complete functional return. Patients with category II injuries required skin grafts for closure; most of these patients (81%) were able to achieve nearly complete functional recovery. Patients with the most severe injuries involving tendons, joints, or bone were assigned to category III; very few of these patients (9%) were noted to have returned to normal function.

The multiple joints and web spaces of the hand are prone to banding and contracture. With regard to reconstruction, three categories should be considered in the hand: soft tissue deformities, joint deformities, and amputations. Contractures of the hand can be classified using the McCauley classification in Table 10-1.³⁸ Release of these contractures follows the standard tech-

Table 10-1 McCauley Classification of Burn Scar Contractures in the Hand	
Grade	Definition
I	Symptomatic tightness but no limitation in range of motion Normal architecture
II	Mild decrease in range of motion without significant impact on activities of daily living No distortion of architecture
III	Functional deficit noted, with early changes in the normal architecture of hand A. Flexion contractures B. Extension contractures C. Combination flexion and extension contractures
IV	Loss of hand function with significant distraction of normal architecture of the hand A. Flexion contractures B. Extension contractures C. Combination flexion and extension contractures

Fig. 10-17 An unusual case of a palmar-burn claw hand. **A** and **B**, Preoperative extent of the deformity. **C-E**, Postoperative views after release using multiple sheet grafts.

niques of Z-plasties, local flaps, and grafts^{39,40} (Figs. 10-17 and 10-18). Because the dorsum of the hand is more likely to be injured, banding typically occurs at the juncture of the burned dorsum and the unburned palmar surface. This is an ideal situation for using Z-plasties, taking advantage of the unburned palmar skin for one limb of the Z-plasty. The Zs are typically placed at the level of the joint crease. The resulting middle limb blends with the naturally occurring crease. Because of its broad expanse, the first web space responds well to either a four-flap Z-plasty or a double-opposing Z-plasty (Fig. 10-19). The other webs are narrower and deeper and usually require a local rotation flap (Fig. 10-20), goalpost flap, or skin graft release (Fig. 10-21), depending on the extent of the contracture and the quality of the surrounding skin.^{41,42}

Dorsal hand burns tend to be more severe than palmar burns, because the skin is thinner and more exposed to injury. The resulting contractures involve hyperextension of the wrist and metacarpophalangeal joints and hyperflexion of the proximal and distal interphalangeal joints. In children this deformity can be tolerated for a long time without significant joint contracture and

Fig. 10-18 A typical dorsal-burn claw hand. **A-C**, Dorsal burn with hyperextension of the metacarpophalangeal joint and hyperflexion of the proximal and distal interphalangeal joints. **D** and **E**, Results after release with skin graft.

Fig. 10-20 Multiple web releases with four-flap Z-plasty to the first web and rotation flaps to other webs. A and B, Markings for a four-flap Z-plasty and rotation flaps. C, Flaps rotated into position. D, Long-term result.

Fig. 10-21 Typical dorsal webbing. **A**, Preoperative view. **B**, Result after release using a full-thickness skin graft.

associated tendon shortening. Correction requires excision of scarred skin to restore transverse and longitudinal hand arches, preservation of the underlying peritenon, internal fixation of the metacarpophalangeal joints at 80 degrees and of the interphalangeal joints at 180 degrees, and coverage with thick sheet grafts. With joint contracture and shortening of the musculotendinous unit or exposure of joints or tendons, flap coverage is necessary for effective treatment.

Although surgeons can perform open releases of the joints and lengthen tendons, the trend is toward excision of the burn scar contracture, coverage with a flap (typically a groin or abdominal flap), and placement of an adjustable external fixator, followed by gradual distraction of the shortened deep structures for necessary lengthening.^{43,44} This can be done for either dorsal or palmar contractures.

Digital contractures are common sequelae of hand burns involving the dorsum of the hand and digits.⁴⁵ Boutonnière deformities occur easily, because the dorsal skin over the proximal interphalangeal joints that protects the central slip is thin. A full-thickness burn in this area immediately exposes the central slip, allowing it to become necrotic and exposing the underlying joint to infection. In severe burn cases these joints are often overlooked because the focus is on lifesaving and resurfacing issues. Ideally, surgeons should perform early debridement followed by flap reconstruction to preserve the underlying tendon and joint structures.^{46,47} However, this is usually not practical, except for isolated burn injuries. Typically, surgeons see chronic burn boutonnière deformities in the convalescent period. Treatment depends on the condition of the proximal interphalangeal joint, and radiographs should be obtained. Fixed deformities and the fingers with joint destruction are best treated with fusion of the proximal interphalangeal joint.⁴⁸ If a finger has normal range of motion and the joint is normal, the surgeon can attempt correction with reattachment of the central slip and centralization of the lateral bands. This usually requires antecedent reconstruction of the joint's dorsal surface with a flap. Interdigital contractures (burn syndactyly) rarely cause significant functional deficits unless they involve the first web space. Z-plasties are associated with lowest recurrence of syndactyly, whereas skin grafts and flaps have a higher rate.³⁸

The thumb represents about 50% of the function of the hand. Burn injuries can result in complete or partial loss of digits and compromised function. Reconstruction of the thumb is the

Fig. 10-22 Toe-to-hand transfer to reconstruct a thumb. **A-C**, Postoperative result. **D**, Donor defect.

basis for successful rehabilitation of the hand. Concerns in thumb reconstruction include preservation of length, mobility, sensibility, and stability. During the acute period, care is needed to preserve the first web space and prevent contracture and palmar adduction. Burn injuries often result in the loss of digits or portions of digits (length), which causes problems with pinch, grasp, and opposition. With loss of thumb and digital length, a number of options are available to restore function. Treatment of web space contractures has already been discussed, but the first web may also have to be deepened to provide mobility and opposition. Phalangization involves deepening the first web by resecting the second metacarpal (with the loss of the index finger).³⁸ This effectively converts the thumb metacarpal and its residual phalanx into a phalanx, allowing some degree of pinch and opposition. If a residual proximal phalanx is present on the index finger, it can be transferred on its neurovascular pedicle to the thumb to lengthen the thumb. This procedure is known as an *on-top-plasty*, which works especially well if the thumb has been lost at the metacarpal phalangeal level.⁴⁹ In rare circumstances with total loss of the thumb with preservation of the index finger, a formal pollicization can be performed.⁵⁰ However, severe injuries are more likely to require a toe-to-hand microvascular transfer⁵⁰ (Fig. 10-22). These can be singular (classic great toe or second toe) or multiple (great toe for the thumb and second toe for a digit to oppose). Preoperative planning may require release of the first web and adequate soft tissue to cover the base of the thumb. Usually a groin flap is placed to accomplish these objectives. Stability issues are typically corrected with joint fusion. Complex reconstructions require adequate healthy soft tissue, which is usually at a premium.

Nail and nail bed injuries can be particularly difficult to treat.⁵¹ Burn injuries destroy and distort the germinal matrix, resulting in painful nail remnants buried in scar tissue. These can be

difficult to eradicate. Treatment is excision of the remaining matrix, but this can be elusive. Another common problem is scar causing retraction of the eponychial fold. This can be painful and cause distortion of the nail bed. Improvement occasionally can be accomplished by releasing the retracted eponychium and placing a skin graft behind the fold. More severe cases may require an advancement or rotation flap of the dorsal or lateral skin to replace the cutaneous portion of the fold and grafting the donor site.⁵²

Lower Extremities

The lower extremities constitute more than 30% of the entire body surface area. The reconstructive approach of the lower extremity is based on the amount and depth of tissue destroyed and follows general principles that apply elsewhere in the body. The pediatric burn population requires special planning for continued growth and probably repeated surgical intervention.

Contractures are most likely to occur across joints (for example, the knees, ankles, and toes). The most common lower extremity deformities that require correction in burn patients are dorsal foot extension contracture, popliteal flexion contracture, and hip flexion contractures.

Scar contracture of the dorsum of the ankle should be released and covered with a split-thickness skin graft. Long-standing contracture can cause shortening of the extensor tendons. Contracture of the posterior ankle universally involves the calcaneal tendons. The use of local flaps in the burned lower extremity is challenging when local donor tissue is limited (Fig. 10-23).

Contracture at the knee is more common than at the ankle. Knee joint contractures, however, are far more easily prevented than those affecting any other lower extremity joint.⁵³ Linear and narrow scar bands may be released and lengthened by a Z-plasty. Wider and thicker scars will have to be released, partially excised, and resurfaced with skin grafts or occasionally by flaps. Reconstruction must be designed so that the desired functional and aesthetic results can be achieved using the simplest method available and with minimal donor tissue or donor site morbidity. To prevent recurrence of contracture, splinting the knee in the extended position is necessary for 2 to 6 months.

For severe injuries that require below-knee amputation, every effort should be made to preserve the knee joint, including the use of free flaps, both soft tissue and osteocutaneous, if length is a problem. In growing children, subsequent growth of the residual tibia may cause repeated ulceration and breakdown, necessitating repeated revisions.

Fig. 10-23 Dorsal ankle and toe release. **A**, Immediately following ankle release after a dorsal toe release. **B**, Final result.

One of the most common problems seen in children is dorsal toe contractures from burns of the dorsum of the foot. Treatment involves release, pinning the toes, and coverage with a skin graft. The pins are removed at 7 to 10 days, and the foot is placed in a shoe with metatarsal bars. Pressure is applied using garments with foam or silicone inserts. Reconstruction of the plantar surface remains a challenge. The unique nature of both plantar and palmar skin, with fibrous connections to deeper structures, prevents shifting of the overlying skin and enhances stability. Loss of this unique property and loss of the associated sensation in weight-bearing areas can cause breakdown, ulceration, and exposure. Although free flap reconstruction may be necessary for deep dermal burns of the plantar surface, it will lack stability and be prone to breakdown and ulceration. Every effort should be made to preserve the weight-bearing portions of the foot.

Genitalia

Perineal burns and injury to external genitalia can occur from a number of sources. With infants, dipping and scald burns frequently involve the perineum and its structures. Males are at a greater risk and generally experience more problems than females because of the inherent differences in genital structure. In the acute phase, problematic contracture is limited by inserting a Foley catheter, splinting the patient in an abducted position, and conservative management of damaged genital tissue.

Perineal contracture is the most common delayed complication. This can be treated conservatively with the appropriate use of Z-plasties and skin grafts to release bands and resurface.⁵⁴ Females commonly have webbing or banding crossing the labia majora; a good outcome can be achieved with standard reconstruction techniques. Although meatal issues are common in males from both the burn injury and the Foley catheter, they rarely occur in females.^{41,42} Loss of the penis, scrotum, testicles, or any combination is possible. The testicles can retract, and combined with subsequent scarring, can appear to be cryptorchid. Scrotums can be reconstructed by bringing down the testicles, pexing them together, and covering them with skin grafts. This is preferable to burying them in the medial thigh, because spermatogenesis takes place below body temperature. Full-thickness burns to the penile shaft can be resurfaced using split-thickness grafts, preferably from a non-hair-bearing area, and appropriate splinting.^{42,55} With total loss of the penile shaft, reconstruction usually requires a free tissue transfer, typically a radial forearm flap (Fig. 10-24).

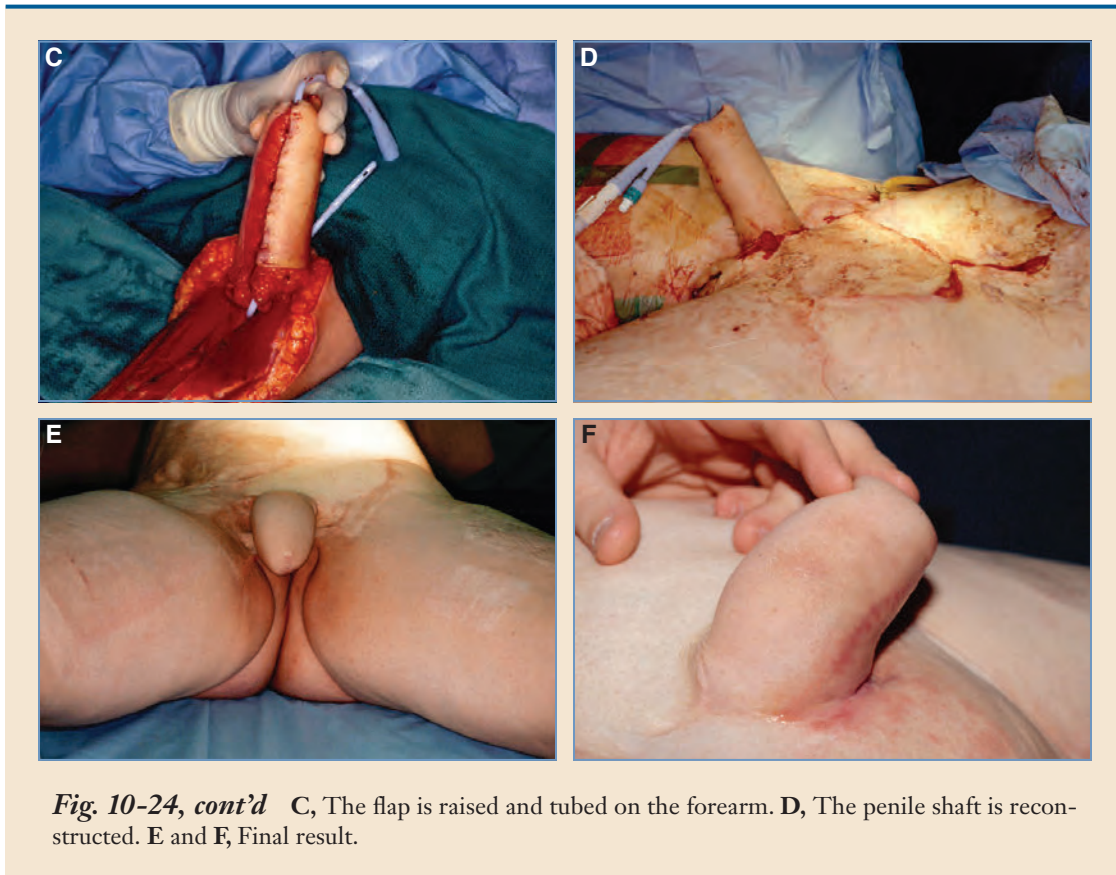

Fig. 10-24 Loss of penile shaft after a muffler burn. **A**, Preoperative defect. **B**, The plan is outlined on the forearm.

Continued

Scar Band Release

Scar bands are sequelae of healing burns that can cause disfigurement and restriction of motion and/or function. In children they tighten during periods of rapid growth. Scar bands that are candidates for release are those that remain tight beyond the growth spurt, especially if they result in a measurable decrease in range of motion. To determine whether a scar release will require subsequent grafting and local or distant flaps, the anatomic site, adjacent tissue, and degree of contracture are considered. The sequence of treatment for scar bands should be managed proximally to distally (for example, the axilla, then the elbow, wrist, hand, and fingers). Contractures can be simultaneously released at multiple levels during the same procedure. Combinations involving skin grafts and local flaps provide versatility in managing scar bands. Scar bands in joint lines are especially well managed with Z-plasty flaps.³

When a scar band release is planned, it is almost always necessary to carry the release incision into the adjacent unscarred skin to achieve adequate improvement in excursion. Postrelease grafts require splinting and pressure treatment, similar to acute burn grafting. A burn therapist should be consulted preoperatively to ensure the postoperative therapy goals reflect the surgical plan. Scar contracture releases that expose joints, tendons, or critical structures will require coverage with distant, pedicled, or free flaps, especially in the hand.

SOCIETAL REENTRY AND SCHOOL INTEGRATION

The period of reentry into society and school is critical for children who have had reconstruction of burn injuries. Not only do they have additional physical and medical needs, but they also have significant psychological requirements. These profound needs and changes can be best addressed with a coordinated reentry program. The burn team should meet with both the parents and school staff to discuss the child's special needs. With appropriate communication, preparation, and education, the process will be greatly eased. The need for continuing medical needs, wound care, splints, and garments should be emphasized. Appropriate precautions and specific methods for dealing with blisters, cuts, and minor wounds should be instituted with teachers and school health staff. The need for ongoing physical therapy and medical appointments may lead to missed classes. It is important to educate classmates and teachers about the child's appearance and injuries. This can preempt derogatory comments or questionable behavior by the students. Visual aids are helpful to explain the injury and its treatment, and time should be set aside to answer questions and concerns. School counselors should be heavily involved to help the child and his or her peers.

KEY POINTS

- Of the 6.6 million major burn injuries that occur each year, approximately half occur in children.
- The most vulnerable pediatric age group susceptible to burn injury is children younger than 5 years of age. Scald, contact, and electrical injuries are most common among children.
- It is estimated that about 20% of pediatric burns are the result of abuse or neglect.
- The potential for hypertrophic or keloid scarring is largely unpredictable; however, there are many risk factors for abnormal scarring in a burn injury.
- The most reliable and proven modality for preventing or treating abnormal burn scars is the use of pressure.
- Improved survival from major burns has led to increased and more complex secondary burn deformities that can significantly affect aesthetics and function.
- The reconstructive approach of the lower extremity is based on the amount and depth of tissue destroyed and follows general principles that apply elsewhere in the body.
- Reentry into society and school is critical for children who have burn injuries.

Nasal reconstruction is one of the most important elements in rehabilitation of patients with devastating deformities of full-thickness facial burns. When possible, the authors used a single pedicle for complete nasal reconstruction. The forehead furnished the best donor area. More distant donor sites were used if the forehead was not available. In lesser deformities, resurfacing with composite grafts or full-thickness skin grafts gave satisfactory results.

Tissue expansion is a useful tool for reconstructive burn surgeons. However, high complication rates and many dissatisfying results may occur. This paper looks at a large series of burn-related head and neck reconstructions with tissue expansion. Techniques and refinements were reviewed. Today, head and neck burn reconstruction is accomplished best with a combination of skin grafting, local flaps, and occasional free flaps in addition to tissue expansion.

Vascular Anomalies

Arin K. Greene • John H. Phillips

ascular anomalies are disorders of the endothelium that can affect capillaries, arteries, veins, or lymphatics. They are common, affecting approximately 5.5% of the population.¹ Vascular anomalies are confusing, because numerous types of them exist, lesions often look similar, and imprecise terminology is used.² Vascular anomalies are classified biologically, based on their clinical behavior and cellular characteristics³ (Table 11-1). Using the biologic classification, 90% or more of lesions can be diagnosed by history and physical examination. There are two broad types of vascular anomalies: tumors and malformations.⁴ Tumors demonstrate endothelial proliferation and affect approximately 5% of the population. There are four major types of tumors⁵:

1. Infantile hemangioma
2. Congenital hemangioma
3. Kaposiform hemangioendothelioma (KHE)
4. Pyogenic granuloma

Patients with problematic vascular anomalies are best managed in an interdisciplinary vascular anomalies center.

Table 11-1 Classification of Vascular Anomalies

Tumors	Malformations		
	Slow-Flow	Fast-Flow	Overgrowth Syndromes
Infantile Hemangioma	Capillary Malformation	Arterial Malformation	CLOVES
PHACES association LUMBAR association	CLAPO Cutis marmorata Cutis marmorata telangiectatica congenita Diffuse capillary malformation with overgrowth Fading capillary stain Heterotopic neural nodule Macrocephaly–capillary malformation	Aneurysm Atresia Ectasia Stenosis	KTS Maffucci Parkes Weber Proteus Sturge-Weber
Congenital Hemangioma	Lymphatic Malformation	Arteriovenous Malformation	
Rapidly involuting congenital heman-gioma	Macrocystic and microcystic combined (macrocystic/microcystic) primary lymph-edema Gorham-Stout disease Generalized lymphatic anomaly Kaposiform lymphangiomatosis	Capillary malformation–arteriovenous malformation Hereditary hemorrhagic telangiectasia PTEN-associated vascular anomaly Wyburn-Mason syndrome	
Kaposiform Hemangioendothelioma	Venous Malformation		
	Blue rubber bleb nevus syndrome Cerebral cavernous malformation Cutaneomucosal venous malformation Diffuse phlebectasia of Bockenheimer Fibroadipose vascular anomaly Glomuvenous malformation Phlebectasia sinus pericranii Verrucous venous malformation		
Pyogenic Granuloma			
Rare Vascular Tumors			
Angiosarcoma cutaneovisceral angiomatosis with thrombocytopenia Enzinger intramuscular hemangioma Epithelioid hemangio- endothelioma Infantile myofibroma Tufted angioma			

CLAPO, Capillary malformation of the lower lip, lymphatic malformation of the face and neck, asymmetry of face and limbs, and partial or generalized overgrowth; *CLOVES*, congenital, lipomatous, overgrowth, vascular malformations, epidermal nevi, spinal/skeletal anomalies and/or scoliosis; *KTS*, Klippel-Trenaunay syndrome; *LUMBAR*, lower body hemangioma and other cutaneous defects, urogenital anomalies, ulceration, myelopathy, bony deformities, ano-rectal malformations, arterial anomalies, renal anomalies; *PHACES*, posterior fossa: brain malformations that are present at birth, hemangioma on the skin of the head/neck (>5 cm), arterial lesions: abnormalities of the blood vessels in the head/neck, cardiac abnormalities/aortic coarctation, eye abnormalities, and sternal defects; *PTEN*, phosphatase and tensin homolog.

Vascular Tumors

Vascular tumors generally demonstrate rapid growth, endothelial and angiogenic proliferation, and then postnatal regression. Vascular tumors can be differentiated from vascular malformations by various indicators, such as immunohistologic measures and imaging with MRI and ultrasonography with color flow Doppler imaging.

The International Society for the Study of Vascular Anomalies (ISSVA) classification of vascular tumors divides them into three broad categories: (1) benign, (2) locally aggressive, and (3) malignant.⁶ Benign vascular tumors include infantile hemangiomas, congenital hemangiomas (which are further divided into rapidly involuting [RICH], noninvoluting [NICH] and partially involuting [PICH]), tufted angiomas, spindle cell hemangiomas, epithelioid hemangiomas, and pyogenic granulomas. Locally aggressive vascular tumors include Kaposiform hemangioendothelioma (KHE) and Kaposi sarcoma. Malignant vascular lesions include angiosarcoma (Box 11-1).

Box 11-1 ISSVA Classification of Vascular Tumors

Benign Vascular Tumors

- Infantile hemangioma/hemangioma of infancy
- Congenital hemangioma
 - RICH*
 - NICH
 - PICH
- Tufted angioma
- Spindle-cell hemangioma
- Epithelioid hemangioma
- Pyogenic granuloma (also known as *lobular capillary hemangioma*)
- Others

Locally Aggressive or Borderline Vascular Tumors

- KHE†
- Retiform hemangioendothelioma
- PILA, Dabska tumor
- Composite hemangioendothelioma
- Kaposi sarcoma
- Others

Malignant Vascular Tumors

- Angiosarcoma
- Epithelioid hemangioendothelioma
- Others

*Some lesions may be associated with thrombocytopenia and/or consumptive coagulopathy.

†Many experts think that KHEs are part of a spectrum rather than distinct entities.

NB: Reactive proliferative vascular lesions are listed with benign tumors.

ISSVA, International Society for the Study of Vascular Anomalies; KHE, Kaposiform hemangioendothelioma; NICH, noninvoluting congenital hemangioma; PICH, partially involuting congenital hemangioma; PILA, papillary intralymphatic angioendothelioma; RICH, rapidly involuting congenital hemangioma.

HEMANGIOMAS

Vasculoproliferative tumors are thought to result from the formation of primitive blood vessels from angioblasts. Progenitor cells can be identified in the hemangioma that may originate from the placenta. During proliferation, cellular proliferative factors such as vascular endothelial growth factor (VEGF) are elevated and return to normal levels on involution.⁷⁻⁹ During involution, an increase in the number of mast cells has been seen,¹⁰⁻¹² and mesenchymal stem cells may differentiate into adipocytes in the lesions.^{9,13} During this phase, capillaries undergo apoptosis, which results in resolution.

The expression of glucose transporter 1 (GLUT1) isoform protein is unique to placental endothelial cells and infantile hemangiomas. GLUT1 is not found in congenital hemangiomas such as NICH and RICH.^{14,15} Infantile hemangiomas usually present between 2 weeks and 2 months after birth, and they undergo a proliferative phase, whereas congenital hemangiomas are fully formed at birth.^{14,16}

Infantile Hemangiomas

Hemangiomas are the most common vascular anomaly of childhood.^{17,18} Hemangiomas occur in 20% of low-birth-weight premature infants and are 2 to 4.5 times more frequent in females.¹⁴ Hemangiomas occur in 4% to 5% of white infants but are rare in dark-skinned infants.¹⁴ Placental cells and infantile hemangiomas appear to have a similar life cycle, which suggests that hemangiomas may result from embolized placental cells. The increased risk of hemangiomas in women undergoing procedures that may cause trophoblastic embolization and placental disruption supports the theory of the placental origin of hemangiomas^{19,20} (Fig. 11-1).

Most of these lesions in the skin appear during the first month of life; however, those occurring under the skin may not be noticed until several months after birth and may have a reddish-purple hue when they enlarge (Fig. 11-1, *A*).

During the first 9 to 12 months, these lesions undergo a period of rapid proliferation called the *proliferative phase* (Fig. 11-1, *B*). During the proliferative phase, ulceration and bleeding are common problems for parents. Local wound care by family members is supported by medical staff with regular clinic visits. With ulceration, there is risk for infection and secondary scarring. Bleeding usually responds to light pressure and dressing.

After approximately 12 months, infantile hemangiomas begin to involute and often disappear completely (Fig. 11-1, *C*). Involution is usually complete by 4 years of age.²¹

Infantile hemangiomas are most common in the head and neck region (60%) but can occur anywhere on the body.¹⁴ Hemangiomas on the lumbosacral area have increased risk for spinal dysraphism, tethered cord, and pelvic anomalies. There is also the association of hemangiomas with segmental anomalies. The most common is posterior fossa abnormalities, hemangiomas in the fifth cranial nerve region, arterial intracranial anomalies, cardiac anomalies, eye anomalies, and sternal defects (PHACES) association. There is also LUMBAR association, which stands for *l*ower body hemangiomas, *u*rogenital anomalies, *m*yelopathy, *b*ony deformities, *a*norectal and *a*rtial malformations, and *r*enal anomalies (Box 11-2).

Liver hemangiomas are seen in up to 13% of children with skin lesions, making the liver the most common extracutaneous site.^{14,22} These hepatic hemangiomas may be associated with high-output congestive heart failure as a result of the shunting of blood through the vascular lesion. Other problems rarely associated with infantile hemangiomas may include visual obstruction, nasopharyngeal obstruction, or auditory canal obstruction (Fig. 11-2).

Fig. 11-1 A, Infantile hemangioma in facial skin. B, Infantile hemangioma under the skin in subcutaneous tissue. C, Infantile hemangioma shortly after birth resulting in airway obstruction and the need for a tracheostomy. D, Infantile hemangioma resolving at 3 years of age. E, Infantile hemangioma resolving at 8 years of age.

The most common ocular complication of periocular capillary hemangiomas in infants is visual loss as a result of amblyopia. The strikingly high incidence of amblyopia in some periocular infantile hemangiomas may be related to the onset of the tumor within the first few months of life. Animal research models demonstrate severe amblyopia after only 1 to 4 weeks of visual axis occlusion.²³ Case reviews have reported an incidence of 40% to 60% of amblyopia with periocular capillary hemangiomas.²³⁻²⁵ Vision loss can be caused by strabismus, anisometropia, or visual deprivation. Stigmar²⁴ concluded that the longer the visual axis was occluded, the more severe the amblyopia, reporting that 4 of 51 patients developed moderate to severe amblyopia after only 1 month of occlusion.

In 2008 a group of physicians from Bordeaux Children's Hospital in France described an interesting observation regarding several patients with extensive infantile hemangiomas who received concomitant treatment with propranolol for obstructive hypertrophic cardiomyopathy and high cardiac output.²⁶ Although multiple studies have been reported using propranolol in infantile hemangiomas, there is still no consensus on the optimal dosing regimens and long-term safety profiles.²⁷⁻²⁹

Box 11-2 Regional and Diffuse Associations, Including Vascular Neoplasms**PHACES Association***

- Posterior fossa abnormalities
- Hemangiomas in the fifth cranial nerve region
- Arterial intracranial anomalies
- Cardiac anomalies/coarctation of the aorta
- Eye anomalies
- Sternal defects

LUMBAR Association

- Lower body hemangiomas
- Urogenital anomalies and ulceration
- Myelopathy
- Bony deformities
- Anorectal and arterial malformations
- Renal anomalies

Maffucci Syndrome

- Multiple enchondromas and spindle cell hemangioma
- Hemangioendotheliomas

*Diagnosis requires three or more of these symptoms, one of which must be hemangioma.

Fig. 11-2 Infantile hemangioma of the upper eyelid resulting in visual obstruction.

At The Hospital for Sick Children in Toronto, Ontario, Canada, all children with hemangiomas are assessed by the dermatology service. The exclusion criteria for the use of propranolol was a history of asthma, decreased blood glucose levels, seizures, or suspected PHACES syndrome. The dosage is 0.1 mg/kg/dose tid for 3 days, which is increased to 0.3 mg/kg/dose tid for 3 days, then 0.6 mg/kg/dose tid for 3 days, and finally 0.7 mg/kg/dose for 3 days. Then, if no clinical improvement or worsening has occurred at 2 weeks, the dose should be increased every 2 weeks by 0.5 mg/kg/day, up to a total of 3 mg/kg/day.

There is some controversy with respect to what beta blockade may do to the susceptible developing brain of a neonate. A number of studies in humans indicates that prenatal beta blockade

induces long-term neurologic complications, including impaired school performance, cognitive impairment, and psychiatric disorders^{30,31}; however, no studies to date have examined the long-term neurologic effects of acute or chronic beta blockade in infancy.

Presently the Hospital for Sick Children is using nadolol in patients with infantile hemangiomas, because there is thought to be a decrease in potential side effects compared to propranolol. For weeks 0 to 4, the dosage is 0.5 mg/kg/day divided bid. For weeks 4 to 24, the maintenance phase, the dosage is 2 mg/kg/day. Then there is a deescalation phase during weeks 25 to 52 if there is a complete response or no evidence of proliferation by 10% per week for 4 weeks of weaning. If partial response occurs, a 2 mg/kg/day dosage should be maintained and monitored monthly.

After involution, residual changes may occur, such as residual telangiectasia, skin hypopigmentation, atrophic skin changes, residual skin excess, and fibrofatty tissue. A longer age to involution appears to be related to a greater degree of residual changes. Approximately 10% to 20% of patients require some form of treatment for residual changes.

There is some controversy with respect to the timing of surgery for infant hemangiomas. However, waiting until involution is complete or nearly complete ensures the fewest residual changes present at surgery, including the smallest possible scar with minimal blood loss.

Diagnosis and Imaging

The diagnosis of most infantile hemangiomas is based on history and physical examination, with no imaging studies required. Hemangiomas on grayscale ultrasonography are well defined, solid, and homogeneous, with variable echogenicity. With Doppler ultrasonography, hemangiomas are seen to be hypervascular with arterial and venous wave forms (Fig. 11-3, *A*). MRI shows an intermediate signal on T1-weighted images and a bright signal on T2-weighted images with internal flow voids (Fig. 11-3, *B*).

Fig. 11-3 A, Doppler sonogram of an infantile hemangioma in the proliferative phase showing vascular proliferation. B, MRI of infantile hemangioma in the proliferative phase showing vascular filling voids.

Congenital Hemangiomas

Congenital hemangiomas differ from infantile hemangiomas in that they are fully developed at birth and are negative for the GLUT1 protein. Congenital hemangiomas are less common than infantile hemangiomas and there is no sex predisposition.²⁹

There are three main types of congenital hemangiomas:

1. Noninvoluting congenital hemangiomas (NICHs), which are present at birth and then demonstrate proportional growth without regression (Fig. 11-4, *A* and *B*)
2. Rapidly involuting congenital hemangiomas (RICHs), which are present at birth and generally completely regress by 2 years of age²⁹ (Fig. 11-5, *A-D*)
3. Partially involuting congenital hemangiomas (PICHs), which are usually solitary and present in the head and limbs near a joint²⁹ (Fig. 11-6)

On physical examination, congenital hemangiomas may have a pink or violet color with multiple telangiectasias and a surrounding paler halo (Fig. 11-7).

At involution, a RICH may leave residual atrophic skin, but unlike hemangiomas, a RICH rarely leaves residual fibrofatty tissue.³⁰ Some NICHs may partially involute (PICHs), but they do not completely resolve. Imaging findings of congenital and infantile hemangiomas overlap; therefore the radiologist needs to be aware of the clinical history and appearance of the lesion.

Fig. 11-4 A, NICH as an infant. B, NICH at 18 years of age.

Fig. 11-5 A, RICH at 1 week of age. B, RICH at 6 weeks of age.

Fig. 11-5, cont'd C, RICH at 3 months of age. D, RICH at 7 months of age.

Fig. 11-6 Congenital hemangioma near joint.

Fig. 11-7 NICH with a surrounding halo.

Fig. 11-8 Pyogenic granuloma on the small finger.

Congenital hemangiomas may have more filling voids, indicative of greater vascularity, and may have calcifications that are not seen in infantile hemangiomas.¹⁷ Treatment of RICHs is similar to that for hemangiomas, although surgery is the treatment of choice for NICHs if clinically warranted.

PYOGENIC GRANULOMAS

Pyogenic granulomas are common acquired benign vasculoproliferative lesions of the skin or mucous membranes. They are most often found in the head and neck region when there is no history of trauma or preexisting skin problems. Pyogenic granulomas are usually solitary and bright red, and they result in bleeding, crusting, and ulceration. They may also be pedunculated (Fig. 11-8).

The cause of pyogenic granulomas is unknown. The following factors have been identified as having a possible role to play in their development:

- Trauma: Some cases develop at the site of a recent minor injury, such as a pinprick.
- Drug-induced: Multiple lesions sometimes develop in patients on systemic retinoids (acitretin or isotretinoin) or protease inhibitors.
- Infection: *Staphylococcus aureus* is frequently present in the lesion.
- Viral infection is possible but not proven.
- The mean age at presentation is 6 to 7 years. Thereafter, there is a decrease in incidence with age.³² Pyogenic granulomas represent 0.5% of skin nodules in children.³³
- Hormonal influences: Pyogenic granulomas occur in up to 5% of pregnancies and are rarely associated with oral contraceptives.
- Pyogenic granulomas are more common in women, because of their frequent formation (5%) on the gingiva during pregnancy.³⁴

Pyogenic granulomas generally require some form of treatment, because they typically do not involute. There are many described treatments for pyogenic granulomas such as CO₂ laser, pulsed dye laser, and silver nitrate application. Surgical excision is the treatment of choice.

TUFTED ANGIOMAS AND KAPOSIIFORM HEMANGIOENDOTHELIOMAS

Tufted angiomas and kaposiform hemangioendotheliomas (KHE) are rare, locally aggressive vascular tumors. Although currently classified as separate entities, they may increasingly be recognized as a spectrum of the same pathology. Tufted angiomas and KHEs are considered neoplasms of intermediate malignancy (ISSVA classification) because of infiltrative growth, local aggressiveness, and variable prognosis.

Fig. 11-9 A, KHE on the upper back. B, KHE in the knee area.

Fig. 11-10 Angiogram of KHE in the upper back demonstrating extensive vascularity.

TAs are rare vasoproliferative tumors that present at or shortly after birth. Histologically, they show vascular tufts of closely packed capillaries in a cannonball pattern.³⁵ These lesions occur on the trunk, extremities, head, neck, and retroperitoneum.³⁶ TAs may be associated with Kasabach-Merritt syndrome with thrombocytopenia as a result of platelet sequestration.³⁷ Surgical excision is the main form of treatment.

KHE also presents at or shortly after birth. These lesions often involve large (greater than 5 cm in diameter) areas on the head, neck, and extremities. They usually appear clinically as flat, reddish-purple edematous lesions (Fig. 11-9).

Histologically, KHE has both vascular and lymphatic components consisting of irregular infiltrating nodules of compressed vessels that may extend into surrounding soft tissues. On imaging, KHE is more often associated with numerous flow voids because of multiple arterial and venous vessels (Fig. 11-10).

Tufted angioma and KHE may also be associated with Kasabach-Merritt syndrome, which if present has a poor prognosis, with up to 30% mortality.³⁸ Surgery is difficult because of the

Fig. 11-11 Kaposi sarcoma of the skin, with red and brown blotches.

involvement of multiple tissue planes and important structures. These lesions may be treated with embolization and then surgical resection where possible; however, surgery is not necessary for lesions that are not causing functional problems. Successful treatment of tufted angioma and KHE has been reported with vincristine.^{31,39,40}

KAPOSI SARCOMA

Kaposi sarcoma is a cancer that develops from the cells that line the lymphatic or blood vessels. Kaposi sarcoma usually appears as tumors on the skin or on mucosal surfaces, such as inside the mouth, but tumors can also develop in other parts of the body such as in the lymph nodes (as bean-sized collections of immune cells throughout the body), lungs, or digestive tract. Kaposi sarcoma is caused by infection with a virus called the *Kaposi sarcoma associated herpesvirus* (KSHV), also known as *human herpes virus 8* (HHV8).^{41,42} The abnormal cells of Kaposi sarcoma form purple, red, or brown blotches or tumors on the skin⁴³ (Fig. 11-11).

The skin lesions of Kaposi sarcoma most often appear on the legs or face. Although they may look painful, they usually cause no symptoms. Kaposi sarcoma can cause serious problems or even become life threatening when the lesions occur in the lungs, liver, or digestive tract. Kaposi sarcoma in the digestive tract, for example, can cause bleeding, whereas tumors in the lungs may cause trouble breathing.

Kaposi sarcoma is rarely seen in children, in whom it is associated with HIV infection and transplant-related immunosuppression.⁴⁴⁻⁴⁸ Endemic Kaposi sarcoma occurs in people living in Equatorial Africa and is sometimes called *African Kaposi sarcoma*. KSHV infection is much more common in Africa than in other parts of the world, so the risk of Kaposi sarcoma is higher. Other factors in Africa that weaken the immune system, such as malaria, other chronic infections, and malnutrition, also probably contribute to the development of Kaposi sarcoma, because the disease affects a broader group of people, including children and women.^{43,49,50}

ANGIOSARCOMA

An *angiosarcoma* is a rare malignant neoplasm characterized by rapidly proliferating, extensively infiltrating anaplastic cells derived from blood vessels and lining irregular blood-filled spaces. Angiosarcomas are aggressive and tend to recur locally, spread widely, and have a high rate of lymph node and systemic metastases. Soft tissue angiosarcoma has a peak incidence in the seventh decade of life, although a wide age range of patients—from 5 to 97 years old—can be affected.⁵¹

Angiosarcomas may occur in any region of the body but are more frequent in skin and soft tissue. Approximately 50% of angiosarcomas occur in the head and neck, but they account for less than 0.1% of head and neck malignancies.⁵² Angiosarcomas also can originate in the liver, breast, spleen, bone, or heart.⁵³⁻⁵⁶

Vascular Malformations

Vascular malformations are errors in vascular development that have minimal endothelial turnover; they affect approximately 0.5% of the population. There are four major categories of vascular malformations based on the anomalous vessel or vessels⁵ (see Table 11-1):

1. Capillary malformation
2. Lymphatic malformation
3. Venous malformation
4. Arteriovenous malformation

Malformations are further divided into rheologically slow-flow and fast-flow lesions.

CAPILLARY MALFORMATION

Clinical Features

Capillary malformation (previously referred to as *port-wine stain*) is the most common type of vascular malformation, affecting 0.3% of newborns.⁵⁷ Capillary malformations can be syndromic and/or associated with underlying structural anomalies. The lesion is noticeable at birth and can involve any area of the integument. The pink-purple skin discoloration can cause psychosocial distress. Over time the lesion progresses, and⁵⁸:

- Darkens
- Fibrovascular cobblestoning can occur
- Pyogenic granulomas may develop
- Soft tissue and bony overgrowth can occur underneath the stain

Phenotypes

Capillary Malformation of the Lower Lip, Lymphatic Malformation of the Face and Neck, Asymmetry of the Face and Limbs, and Partial or Generalized Overgrowth (CLAPO)

CLAPO patients have a midline capillary malformation of the lower lip. The lymphatic malformation is typically microcystic and involves the oral cavity. Patients have normal cognitive development and may have localized or diffuse overgrowth.

Cutis Marmorata

Cutis marmorata is an accentuated pattern of normal cutaneous vascularity common in white infants. Transient mottling occurs with a low temperature that disappears on warming.

Cutis Marmorata Telangiectatica Congenita

At birth the skin of a lower limb in an infant with *cutis marmorata telangiectatica congenita* is depressed, purple, and has a reticulated pattern. Ulceration is common, the leg is often hypoplastic, and iliac/femoral stenosis can occur. Improvement occurs during the first year of life; however, atrophy, pigmentation, and ectasia of the superficial veins often persist.

Diffuse Capillary Malformation With Overgrowth

An extensive extremity capillary malformation can cause soft tissue and bony overgrowth of the limb. The lower extremity is more commonly affected than the upper limb. The extremity has increased circumference and may also have axial overgrowth. Orthopedic consultation is obtained to assess for a leg-length discrepancy.

Fading Capillary Stain

A *fading capillary stain* is a birthmark that is also referred to as an *angel kiss* or *stork bite*. It is present in approximately half of white newborns and is located on the forehead, eyelids, nose, upper lip, or posterior neck. No treatment is necessary, because it lightens over the first 2 years of life.

Heterotopic Neural Nodule

A *heterotopic neural nodule* is a parietal/occipital scalp nodule with overlying alopecia, a surrounding capillary malformation, and a ring of long hair. Lesions contain heterotopic leptomeningeal tissue, and half of these lesions extend intracranially. A neurosurgical consultation is obtained if MRI shows dural involvement.

Macrocephaly–Capillary Malformation

Patients with *macrocephaly–capillary malformation* have the following:

- Macrocephaly
- Developmental delay
- Capillary malformation involving the philtrum/upper lip
- Diffuse capillary malformation involving the trunk or extremities
- Neurologic abnormalities are common

Diagnosis

Diagnosis of capillary malformation is made by history and physical examination; imaging and histopathologic assessment are unnecessary. Lesions affect the skin, are present at birth, and slowly darken.

Management

The mainstay of treatment is pulsed-dye laser (595 nm wavelength). This modality improves the appearance of the lesion by lightening its color⁵ (Fig. 11-12). Intervention during infancy or early childhood is recommended, because:

- Superior lightening of the lesion is achieved.
- The risk of darkening and hypertrophy is reduced.
- Psychosocial morbidity is minimized.

Multiple treatments, spaced 6 weeks apart, are often required until the lesion stops making improvement. Pulsed-dye laser is less effective for capillary malformations that have progressed to a dark color with cutaneous thickening.

Capillary malformations typically do not require surgical intervention. Surgical procedures are indicated to correct overgrowth caused by the malformation⁵ (Fig. 11-13). Patients with facial lesions and soft tissue/bony overgrowth undergo labial reduction, excision of localized cutaneous growths, malar contouring, and/or orthognathic correction. Small fibrovascular nodules or pyogenic granulomas can be excised. Trunk or extremity capillary malformation associated with increased subcutaneous adipose tissue can be improved through suction-assisted lipectomy.

Fig. 11-12 Management of capillary malformation using pulsed-dye laser. **A**, This 20-year-old woman had a capillary malformation involving the right face. **B**, The lightened appearance of the lesion after two treatments. (Courtesy of Sheilagh Maguiness, MD.)

Fig. 11-13 Surgical management of capillary malformation. **A**, This 13-year-old girl had a capillary malformation of the upper lip and cheek causing labial overgrowth. **B**, She had improved lip contour 2½ months after transverse mucosal excision of the hypertrophied tissue.

Severe cutaneous thickening and cobblestoning may be resected and reconstructed through linear closure, skin grafts, or local flaps. If an occlusion cannot be corrected with orthodontics, an orthognathic procedure is considered after completion of skeletal growth.

LYMPHATIC MALFORMATION

Clinical Features

Lymphatic malformation is defined by the size of its channels: macrocystic, microcystic, or combined. Lesions are usually noted at birth, although small or deep lymphatic malformations may not become evident until childhood or adolescence after they have enlarged and/or become symptomatic. The most commonly affected sites are the neck and axilla. Lymphatic malformation causes three major problems: psychosocial morbidity, infection, and bleeding.⁵⁹ Intralesional

bleeding results in pain and swelling. Cutaneous vesicles may have malodorous drainage. Oral lesions can cause macroglossia, pain, poor oral hygiene, and caries. Thoracic or abdominal lymphatic malformations may result in pleural, pericardial, or peritoneal chylous effusions. Periorbital lesions can lead to proptosis, ptosis, amblyopia, reduced vision, and blindness. Intestinal lesions may cause malabsorption. Cervicofacial lymphatic malformations often require tracheostomy to maintain the airway. Osseous lymphatic malformations can cause bone destruction or overgrowth.

Phenotypes

Macrocystic Lymphatic Malformation

Macrocystic lesions contain cysts large enough to be accessed by a needle (typically 5 mm or larger) and are amenable to sclerotherapy. The most commonly affected sites are the neck and axilla.

Microcystic Lymphatic Malformation

Microcystic lesions have cysts that are too small to be cannulated by a needle (usually less than 5 mm) and thus cannot be treated by sclerotherapy. These lesions commonly affect the face and extremities and are often associated with cutaneous vesicles that can bleed and leak lymph fluid.

Combined Lymphatic Malformation

Approximately half of lymphatic malformations are not purely macrocystic or microcystic; rather, they contain both macrocysts and microcysts. The greater the macrocystic composition of the lesion, the better the prognosis, because the lesion can be treated with sclerotherapy.

Primary Lymphedema

Primary lymphedema typically results from hypoplastic lymphatic development in an extremity. The condition usually presents in infancy or adolescence and most commonly involves a lower limb. Several germline mutations can cause primary lymphedema, such as those in *VEGFR3*, *FOXC2*, *SOX18*, and *CCBE1*.

Gorham-Stout Disease

Gorham-Stout disease is a progressive lymphatic anomaly that causes osteolysis of bone. Over time the bone resorbs and causes pain, pathologic fractures, and significant morbidity. Bony changes exhibit progressive osteolysis with resorption and cortical loss. The ribs are most commonly affected, followed by the cranium, clavicle, and cervical spine. Lesions have an associated infiltrative soft tissue abnormality at the site of the bone involvement. One half of all patients with Gorham-Stout disease develop pleural effusions and one fourth have splenic and/or hepatic lesions. Management involves interferon and bisphosphonates.

Generalized Lymphatic Anomaly

Generalized lymphatic anomaly is a multisystem disorder affecting noncontiguous areas. Unlike Gorham-Stout disease, osseous lesions show discrete lytic areas/radiolucencies confined to the medullary cavity; progressive osteolysis and cortical loss do not occur. If symptomatic bony destruction is present, patients are given interferon and bisphosphonates.

Kaposiform Lymphangiomatosis

Kaposiform lymphangiomatosis is a variant of a generalized lymphatic anomaly that causes thrombocytopenia and/or tissue hemorrhage. The lesion involves the mediastinum, bone, spleen, and/or retroperitoneum. Treatment includes drainage of symptomatic effusions, pleurodesis,

sclerotherapy, and medical therapy (such as corticosteroids, vincristine, thalidomide, or sirolimus). The prognosis is poor, and the mortality rate is high.

Diagnosis

Ninety percent of lymphatic malformations are diagnosed by history and physical examination. Small, superficial lymphatic malformations do not require further diagnostic workup. Large or deep lesions are evaluated by MRI to⁵:

- Confirm the diagnosis
- Define the type of malformation (macrocytic, microcystic, or combined)
- Determine the extent of the disease

MRI sequences are obtained with fat suppression and gadolinium. On T1 images, cysts are hypointense. After contrast administration, macrocystic lesions only show enhancement of the wall and septa; venous malformations have more diffuse, heterogeneous enhancement.⁶⁰ Lymphatic malformations are more infiltrative than venous malformations. Because lymphatic malformations have a high water content, they are hyperintense on T2 sequences. Macrocystic lymphatic malformations often have fluid levels because of intracystic blood or proteinaceous fluid. Compared with macrocystic lesions, microcystic lymphatic malformations show more ill-defined borders and slightly greater enhancement. Ultrasonography can provide diagnostic confirmation, document intralesional bleeding, and differentiate between macrocystic and microcystic lesions. Histologic confirmation of lymphatic malformation is rarely necessary.

Management

A lymphatic malformation is benign, and thus intervention is not mandatory.⁵ Small or asymptomatic lesions may be observed. Intralesional bleeding is treated conservatively with pain medication. Patients with more than three infections in 1 year are given prophylactic antibiotics. Recently, oral pharmacotherapy using sirolimus has shown promising results for the treatment of severe microcystic lymphatic malformations. Intervention for lymphatic malformation is reserved for symptomatic lesions or large, asymptomatic macrocysts. Large macrocystic lesions are usually treated prophylactically with sclerotherapy before they bleed or become infected, which can make the lesion microcystic and no longer amenable to sclerotherapy. If possible, intervention should be postponed until after 12 months of age, when the risks associated with anesthesia are lower.⁵ Intervention for a lesion causing a visible deformity should be considered before 4 years of age to limit psychological morbidity.⁵

Sclerotherapy

First-line management for a large or problematic macrocystic or combined lymphatic malformation is sclerotherapy^{5,61} (Fig. 11-14). This technique involves aspiration of the cysts and then injection of an inflammatory substance, which causes scarring of the cyst walls and adhesion to each other. Although sclerotherapy does not remove the lymphatic malformation, it effectively shrinks the lesion and alleviates symptoms. Commonly used sclerosants include doxycycline, sodium tetradecyl sulfate, ethanol, bleomycin, and OK-432. Microcystic lymphatic malformations do not respond to sclerotherapy.

Sclerotherapy produces superior results and has lower morbidity compared with resection. Bleomycin causes minimal swelling and is considered for lymphatic malformations in difficult anatomic areas—such as the oral cavity and airway—or for lesions not responsive to other agents. The use of bleomycin has some benefit for microcystic lesions that are not amenable to resection. Small lesions in adolescents or adults may be treated in the office without image guidance.

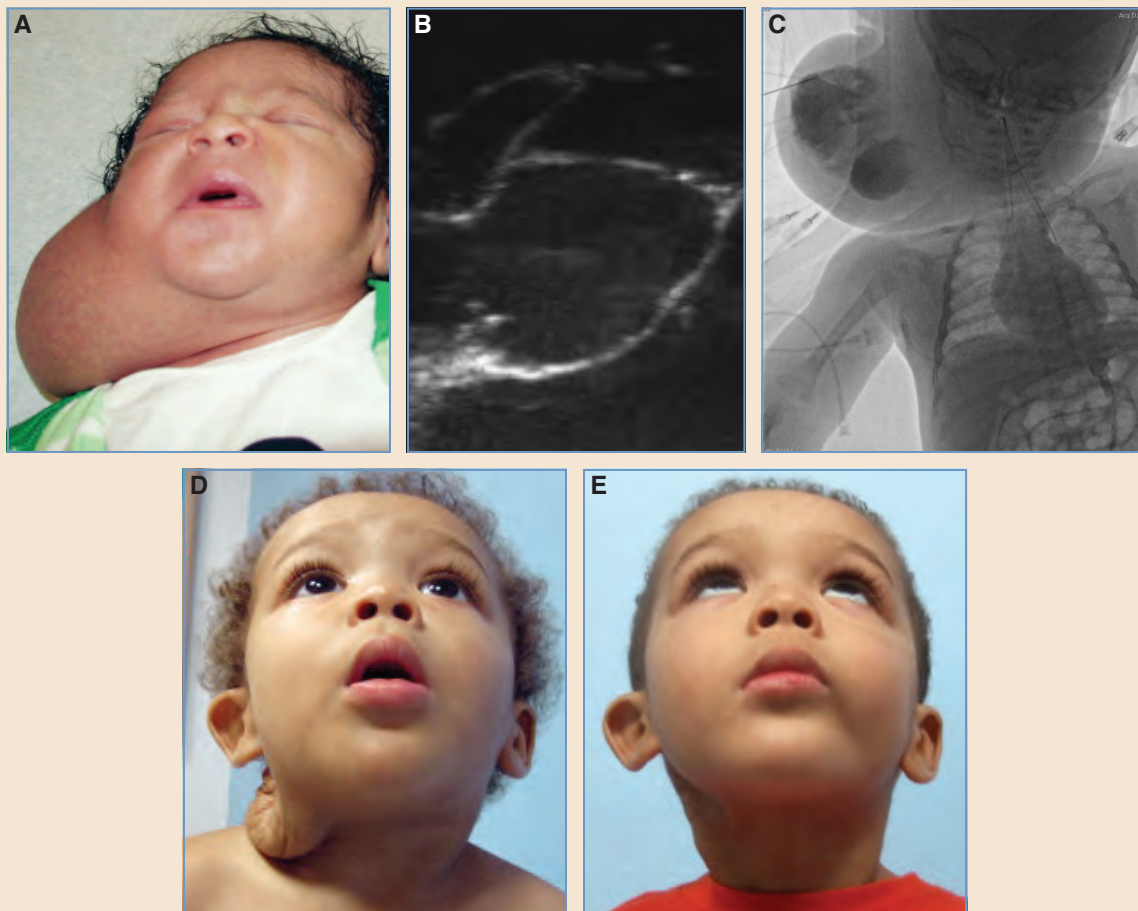

Fig. 11-14 Management of macrocystic lymphatic malformation. **A**, This infant boy had a large lesion involving the neck. **B**, Ultrasound confirmed the presence of macrocysts. **C**, Contrast injection of macrocysts during sclerotherapy. **D**, Two years after sclerotherapy, the child had residual skin excess. **E**, Seven months after resection of redundant skin.

Three percent sodium tetradecyl sulfate is diluted with saline to inject a 1% solution. Most patients, especially children, are managed with a general anesthetic using ultrasonographic and/or fluoroscopic guidance. Large cysts occasionally require placement of a pigtail catheter and sequential drainage and injection over several days.⁵⁹ Additional injections every 6 to 8 weeks may be required. Ulceration is the most common complication of sclerotherapy; it is more likely with superficial lesions and when ethanol is used.

Radiofrequency Ablation

Radiofrequency ablation uses low-temperature tissue destruction that limits thermal injury to the surrounding structures. It is used to treat problematic mucosal vesicles in the oral cavity. Compared with CO₂ laser, radiofrequency ablation provides patients with a faster recovery and less postoperative edema. Reduced swelling is preferable in the oral cavity, because patients can more

Fig. 11-15 Management of microcystic lymphatic malformation. **A**, This 7-year-old boy had a diffuse microcystic lymphatic malformation of the lower extremity causing bleeding and drainage. **B**, Intraoperative image after resection and split-thickness skin graft placement. **C**, Healed skin graft 6 months postoperatively.

easily resume feeding and there is less risk of airway compromise. The low-frequency mode removes a superficial layer of tissue, and the high-frequency option targets deeper structures.

Resection

Resection of a macrocystic lymphatic malformation generally is not indicated, unless: (1) the lesion is symptomatic and sclerotherapy is no longer possible, because all of the macrocysts have been treated or (2) excision may be curative, because the lesion is small and well localized.⁵ Resection is usually subtotal, because lymphatic malformations typically involve multiple tissue planes and important structures. Nonproblematic microcystic malformations can be observed. Extirpation is reserved for symptomatic lesions, because⁵:

- The excision is usually subtotal
- Recurrence is common
- The scar occurs in the area of the malformation
- The patient can have complications from the procedure

Bleomycin sclerotherapy is often attempted before resection of a microcystic lesion in an unfavorable location. Occasionally, bleomycin can improve the appearance of a facial lesion by 10% to 15% and obviate the need for surgical intervention. When considering resection, the surgeon should ensure that the postoperative scar or deformity after removal of the lymphatic malformation should not be worse than the preoperative appearance of the lesion.⁵ For diffuse lymphatic malformations, subtotal excisions of problematic areas, such as bleeding vesicles or an overgrown lip, should be carried out rather than attempting a “complete” removal, which would result in a worse deformity than the malformation itself.⁵ Most wounds are amenable to linear closure through advancing skin flaps. Skin grafts may be necessary to cover large areas⁵ (Fig. 11-15). Bleeding or leaking vesicles may be treated by CO₂ laser, sclerotherapy, or resection.

VENOUS MALFORMATIONS

Clinical Features

Venous malformations contain veins that are dilated with thin walls and abnormal smooth muscle. Consequently, lesions expand, flow stagnates, and clotting occurs. Although venous malformations are present at birth, they may not become evident until childhood or adolescence when they have grown large enough to cause a visible deformity or symptoms.⁶² Lesions are blue, soft, and compressible. Hard, calcified phleboliths may be palpable. Venous malformations range from small, localized skin lesions to diffuse malformations involving multiple tissue planes and vital structures. Almost all lesions involve the skin, mucosa, or subcutaneous tissue; approximately 50% of lesions also affect deeper structures. Ten percent of patients have multifocal, familial lesions. The primary morbidity of venous malformation is psychosocial, because most lesions affect the skin and cause a deformity. The second most common complication is pain caused by thrombosis and phlebolith formation. Stagnation within a venous malformation causes localized intravascular coagulopathy and thrombosis. Symptoms resolve after the phlebolith is resorbed. Patients with venous malformations are not at risk for thromboembolism, unless a large phlebectatic vein is connected to the deep venous system. Head/neck lesions can result in mucosal bleeding or airway compromise. Venous malformations in the extremities can cause a leg-length discrepancy, hypoplasia, pathologic fracture, hemarthrosis, and degenerative arthritis. Venous malformations involving muscle may result in fibrosis, pain, and disability. Gastrointestinal lesions can cause bleeding and chronic anemia.

Phenotypes

Blue Rubber Bleb Nevus Syndrome

Blue rubber bleb nevus syndrome is a rare, nonhereditary disease with multiple small venous malformations involving the skin, soft tissue, and gastrointestinal tract. Three fourths of individuals with gastrointestinal involvement have bleeding that requires blood transfusions. Resection of intestinal lesions may be required.

Cerebral Cavernous Malformation

Cerebral cavernous malformation is an autosomal dominant disorder with venous malformations involving the brain and spinal cord. The condition results from a mutation in *CCM1/KRIT1*, *CCM2/malcavernin*, and/or *CCM3/PDCD10*.⁶³ Patients are at risk for the development of new intracranial lesions, seizures, and hemorrhage. Nine percent of these patients have a hyperkeratotic vascular malformation of the skin.

Cutaneomucosal Venous Malformation

These small, multifocal mucocutaneous lesions of *cutaneomucosal venous malformation* are caused by a mutation in the *TIE2* receptor; this condition is autosomal dominant. Lesions are small and multiple, and typically affect the skin and oral mucosa, but they also may be located in the muscle, brain, lung, and gastrointestinal tract.

Diffuse Phlebectasia of Bockenheimer

Diffuse phlebectasia of Bockenheimer is an extensive venous malformation affecting all tissues of an extremity. The limb is often hypoplastic. Hemarthropathy causing arthritis and joint destruction can occur. Pain may improve with targeted sclerotherapy to symptomatic areas. Joint disease is managed with arthroscopic resection and/or intraarticular sclerotherapy.

Fibroadipose Vascular Anomaly

Fibroadipose vascular anomaly is a lesion that typically affects the calf, followed by the thigh, forearm, gluteal area, and ankle/foot.⁵ It is differentiated from an intramuscular venous malformation by many characteristics:

- Significant pain
- Contractures
- A nonspongiform venous cutaneous component
- Poor response to sclerotherapy

MRI characteristics of fibroadipose vascular anomaly include:

- Fat/fibrosis
- Minimal brightness on T2 images
- Heterogeneous appearance
- Small, poorly defined channels
- Nonspongiform vessels

Management of fibroadipose vascular anomaly consists of physical therapy, corticosteroid injection, sclerotherapy (only if phlebectasia is present), and/or resection.⁵

Glomuvenous Malformation

Glomuvenous malformation is an autosomal-dominant condition that is caused by a mutation in the *glomulin* gene.⁶³ Lesions are typically multiple, small, and located on the extremities. The lesions are more painful than lesions resulting from a sporadic venous malformation.

Phlebectasia

Phlebectasia involves dilation or varicosity of a vein. There are three forms of an abnormally dilated vein: sporadic, associated with lymphatic malformation, and syndromic, such as a lateral embryonal vein. Problematic phlebectatic veins are usually treated with sclerotherapy, although endovascular laser and excision are other options.

Sinus Pericranii

Sinus pericranii is a venous anomaly of the scalp or face that can have transcalvarial communication with the dura. Before resection of a soft tissue lesion, transcranial veins are obliterated endovascularly to prevent intracranial thrombosis.

Verrucous Venous Malformation

Verrucous venous malformation is a hyperkeratotic venous malformation that has also been referred to as *verrucous hemangioma*. It typically affects the skin/subcutis of the lower extremity. Over time it becomes more hyperkeratotic and bleeds. Treatment is through either CO₂ laser or resection.

Diagnosis

Ninety percent of venous malformations are diagnosed through history and physical examination. Patients and families are queried about a family history of similar lesions. Dependent positioning will cause a venous malformation to enlarge. Small, superficial venous malformations do not require additional diagnostic workup. Large or deep lesions are evaluated by MRI to confirm the diagnosis and define the extent of the malformation.⁶² MRI sequences are obtained with fat suppression and contrast. Lesions are hypointense or isointense on T1 images and hyperintense on T2 sequences.⁶⁰ Phleboliths demonstrate a low-intensity signal. Contrast helps delineate a venous malformation from a lymphatic malformation, because venous lesions enhance uniformly. Morphologically, venous malformation is often circumscribed, lobulated, and isolated to an anatomical structure, usually muscle.⁶² Ultrasonography can be used instead of MRI to image

some localized venous malformations and does not require sedation in young children. Histopathologic diagnosis of venous malformation is rarely necessary.

Management

For patients with a venous malformation on a large extremity compression garments are prescribed to reduce stagnation of blood, phlebolith formation, and pain. Individuals with recurrent discomfort are given low-dose daily aspirin to prevent phlebothrombosis.⁶² Large lesions are at risk for coagulation of stagnant blood and localized intravascular coagulopathy. The chronic consumptive coagulopathy can cause either thrombosis and phlebolith formation or bleeding, such as hemarthrosis.⁶² Venous malformations are not at risk for thromboemboli, because they do not affect the deep venous system, and thrombosed lesions are sequestered from larger veins. However, extensive anomalies of the deep venous system or phlebectasia can cause thromboemboli. Patients at risk for thromboemboli are given low-molecular-weight heparin, and occasionally a vena cava filter is necessary.

Venous malformation is a benign condition in which nonproblematic lesions can be observed. Intervention for a venous malformation is reserved for symptomatic lesions or asymptomatic phlebectatic areas at risk for thromboembolism.⁵ If possible, intervention should be postponed until after 12 months of age, when the risks caused by anesthesia are lowest. Therapy for lesions causing a visible deformity should be considered before 4 years of age to limit psychological morbidity.⁵

Sclerotherapy

Sclerotherapy involves the injection of a sclerosant into the venous malformation, causing cellular destruction, thrombosis, and inflammation. Scarring leads to shrinkage of the lesion. This technique typically is first-line treatment for a problematic venous malformation and is generally safer and more effective than resection.⁶¹ Exceptions to this rule include small and well-localized lesions that can be easily excised for cure, glomuvenous malformations that respond less favorably to sclerotherapy, and venous malformations involving the volar hand or adjacent to an important nerve.⁵ Venous malformations involving the palmar surface of the hand are best treated surgically, because if sclerotherapy were to be performed first, fibrosis could prohibit later surgical intervention, because it would increase the difficulty and risks of the procedure. Sclerotherapy effectively reduces the size of the malformation and alleviates symptoms. Sclerotherapy is continued until symptoms are resolved and/or spaces are no longer available to inject. Often multiple treatments are required, spaced 6 weeks apart. Diffuse venous malformations are managed by targeting specific symptomatic areas. Possible sclerosants include sodium tetradecyl sulfate, ethanol, polidocanol, ethanolamine oleate, or an alcohol solution of zein, bleomycin, and sodium morrhuate. Our center prefers sodium tetradecyl sulfate.⁶² Most patients, especially children, are managed using a local anesthetic with ultrasound and/or fluoroscopic guidance. Small lesions in adolescents and adults may be treated in the office without image guidance. Because sclerotherapy does not remove the malformation, patients can continue to have a deformity after treatment that may be improved by resection.

Resection

Extirpation of a venous malformation can be associated with significant morbidity. Resection should be considered for the following⁵:

- Small, well-localized lesions that can be completely removed
- Persistent symptoms after the completion of sclerotherapy
- Lesions involving the volar hand or near an important nerve in which scarring from sclerotherapy would increase the risks of later surgical intervention

When considering resection, the surgeon should weigh the postoperative scar/deformity after removal of the venous malformation against the preoperative appearance of the lesion. Almost all venous malformations should have sclerotherapy before surgical intervention to facilitate the resection, improve the outcome, and lower the recurrence rate. After sclerotherapy, the venous malformation is replaced by scar tissue; thus the risk of blood loss, iatrogenic injury, and recurrence is reduced.

In addition, fibrosis facilitates resection and reconstruction⁵ (Fig. 11-16). Small, well-localized venous malformations may be removed without preoperative sclerotherapy. Gastrointestinal venous malformations with chronic bleeding are typically managed by resection, although solitary lesions can be treated by endoscopic banding or sclerotherapy. A localized venous malformation may be excised and the wound edges reapproximated without complex reconstruction.

For diffuse malformations, staged resection of defined regions is recommended. Subtotal resections of problematic areas, such as bleeding lesions or an overgrown lip, should be carried out rather than attempting a “complete” excision of a benign lesion, which would result in a worse deformity than the malformation itself.⁵

Patients and families are counseled that venous malformations can expand after the excision; thus additional surgical intervention may be required.

Fig. 11-16 Management of venous malformation. **A**, This 5-year-old boy had a venous malformation of the lower lip. **B** and **C**, Contrast injection of the lesion during sclerotherapy. **D**, He has improved lip contour after three sclerotherapy treatments. Additional sclerotherapy was not possible, because accessible vascular channels had been obliterated. **E**, Six weeks after excision of residual fibrotic venous malformation using a transverse mucosal incision.

ARTERIOVENOUS MALFORMATION

Clinical Features

An *arteriovenous malformation* (AVM) has an absent capillary bed that causes shunting of blood directly from arterial circulation to venous circulation through a *fistula* (direct connection of an artery to a vein) or *nidus* (abnormal channel bridging the feeding artery to the draining veins).⁶⁴ Although present at birth, an AVM may not become evident until childhood, after it has enlarged or become symptomatic.⁶⁵ Lesions have a pink-red cutaneous stain, are warm, and can have palpable pulsations. Arteriovenous shunting reduces capillary oxygen delivery causing ischemia. Patients are at risk for pain, ulceration, bleeding, and congestive heart failure. AVMs also can cause disfigurement, destruction of tissues, and obstruction of vital structures. AVMs progress over time and are classified according to the Schobinger staging system⁵ (Table 11-2).

Phenotypes

Capillary Malformation–Arteriovenous Malformation

Capillary malformation–arteriovenous malformation is an autosomal dominant condition exhibiting atypical capillary malformations that are small, multifocal, round, pinkish-red, and usually surrounded by a pale halo.⁶⁴ Handheld Doppler shows fast-flow. The condition is caused by a mutation in *RASA1*. One third of children with capillary malformation–arteriovenous malformation also have an AVM. MRI of the brain and spine is performed to rule out AVMs in these areas.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia is an autosomal dominant condition that is also referred to as *Osler-Weber-Rendu syndrome* and is caused by mutations in endoglin (*ENG*) and activin A receptor type II-like 1 (*ACVRL1/ALK1*). Clinical findings consist of epistaxis, mucocutaneous telangiectasias, visceral AVMs, and a first-degree relative with the condition. Morbidity can include:

- Upper gastrointestinal bleeding
- Stroke and brain abscesses from pulmonary arteriovenous shunting
- Hemorrhage from a cerebral AVM
- High-output heart failure or portal hypertension from a hepatic AVM
- Chronic anemia typically from epistaxis

PTEN-Associated Vascular Anomaly

Patients with *PTEN* mutations have *PTEN hamartoma-tumor syndrome* (previously called *Cowden syndrome* or *Bannayan-Riley-Ruvalcaba syndrome*).⁶⁴ Half of these individuals have a fast-flow vascular anomaly with arteriovenous shunting, referred to as a *PTEN-associated vascular anomaly*.

Table 11-2 Schobinger Staging of Arteriovenous Malformation

Stage	Clinical Findings
I (Quiescence)	Skin warm, pink-blue, shunting on Doppler
II (Expansion)	Enlargement, pulsation, thrill, bruit, tortuous veins
III (Destruction)	Dystrophic skin changes, ulceration, bleeding, pain
IV (Decompensation)	Cardiac failure

(PTEN-AVA).⁶⁴ PTEN-AVAs can be multifocal, contain ectopic adipose tissue, and have segmental dilation of draining veins. Patients with this syndrome exhibit macrocephaly and males have penile freckling. Other features can include developmental delay/autism, thyroid lesions, and/or gastrointestinal polyps. Patients with a PTEN mutation are followed for the presence of tumors, particularly endocrine and gastrointestinal malignancies. PTEN-AVAs are managed similarly to nonsyndromic AVMs.

Wyburn-Mason Syndrome

Wyburn-Mason syndrome is a condition that has also been called *Bonnet-Dechaume-Blanc syndrome* and *retinocephalofacial vascular malformation syndrome*.⁵ The syndrome consists of retinal AVMs with or without brain AVMs and a facial capillary malformation or AVM.

Diagnosis

Ninety percent of AVMs are diagnosed by history and physical examination. Hand-held Doppler examination shows fast-flow. If the diagnosis is equivocal after history, physical examination, and handheld Doppler, ultrasound is the first-line study to confirm the diagnosis. Color Doppler shows a poorly defined hypervascular lesion with fast-flow and shunting; a parenchymal mass is not present. Tortuous feeding arteries are visualized with dilated draining veins and significant flow. MRI is usually obtained to confirm the diagnosis and determine the extent of the lesion. AVMs exhibit dilated feeding arteries/draining veins, enhancement, and flow voids.⁶⁰ Magnetic resonance angiography (MRA) shows feeding arterial vessels and early enhancement of draining veins. An angiogram is obtained if the diagnosis remains unclear after ultrasound and MRI, or if embolization is planned. Angiography shows the flow dynamics of the lesion and identifies the dilated arteries, the enlarged draining veins, and the nidus. The nidus contains tortuous, small vessels with ill-defined vascular spaces. Histopathologic diagnosis of AVM is rarely necessary.

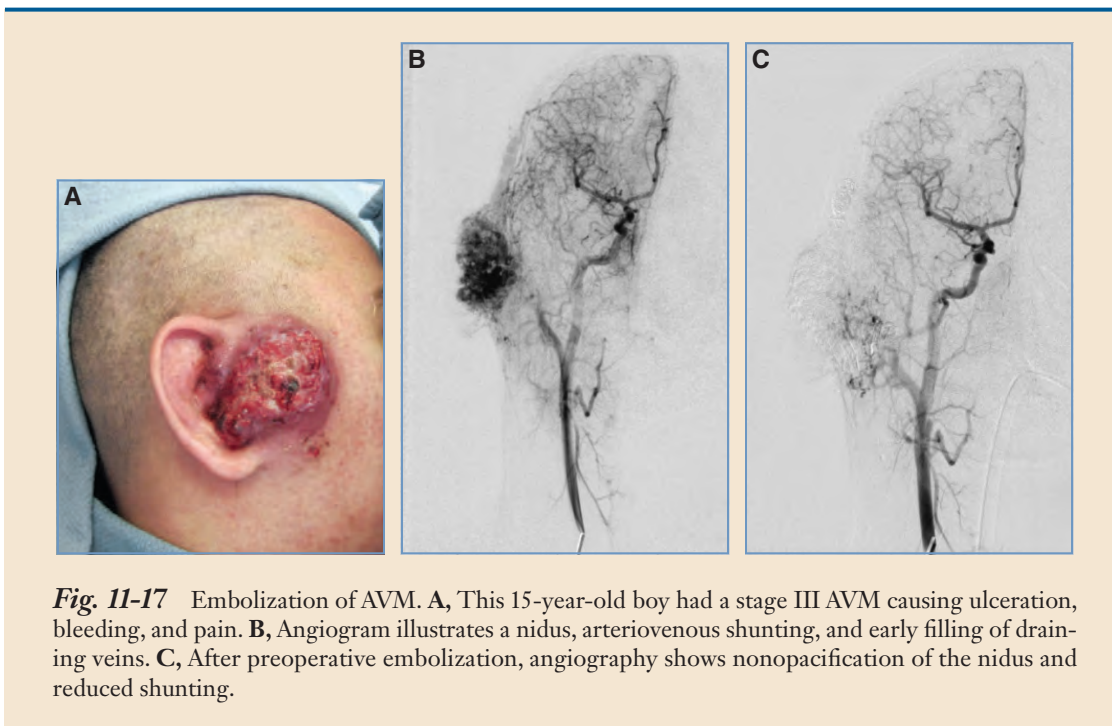

Management

AVM is not a malignancy and intervention is not mandatory.⁵ Management is focused on alleviating symptoms, preserving vital functions, and improving a deformity. Because the lesion is often diffuse and involves multiple tissue planes, a cure is rare. An asymptomatic AVM should be observed unless it can be removed for possible cure with minimal morbidity.⁵ Embolization or incomplete excision of an asymptomatic lesion may stimulate it to enlarge and become problematic. Intervention must be individualized based on the degree of deformity that would be caused by excision and reconstruction.

For example, a stage I AVM in a location that is not anatomically important may be easily resected before it progresses to a higher stage when excision is more difficult and the recurrence rate is greater. In contrast, a large asymptomatic AVM on the face is easily noticeable, especially in a young child who is not psychologically prepared for a major procedure.⁶⁵ Resection and reconstruction may result in a more noticeable deformity or functional problem than the malformation itself. Intervention for a stage II AVM is similar to that of a stage I lesion, although the threshold for treatment is lower if an enlarging lesion is causing a worsening deformity or if functional problems are expected.⁶⁵ Stage III and IV AVMs require intervention to control pain, bleeding, ulceration, or heart failure.

Embolization

Embolization is the delivery of substance through an arterial catheter to occlude blood flow and/or fill a vascular space. Success requires that the embolic agent reaches the nidus of the AVM at

the point of initial venous drainage.⁶⁶ In addition to the replacement of arterialized blood with an inert embolic substance, ischemia and scarring further reduce arteriovenous shunting, shrink the lesion, and improve symptoms. Embolization is not curative, and most AVMs will reexpand after treatment.⁶⁵ Indications for embolization include preoperative intervention to reduce blood loss during resection (Fig. 11-17) or definitive treatment to alleviate symptoms for lesions not amenable to resection.⁵ Proximal arterial embolization is contraindicated, because recanalization occurs and the lesion becomes inaccessible for future embolization. Because the AVM is not removed, almost all lesions eventually will expand after treatment.⁶⁵ Embolization can effectively palliate an AVM by alleviating pain and bleeding. Substances used for embolization may be liquid (N-butyl cyanoacrylate, Onyx, ethanol) or solid (polyvinyl alcohol particles, coils).⁶⁶ The most frequent complication of embolization is ulceration, which is more common for superficial lesions. Distal migration of embolic material can cause ischemic injury to uninvolved tissues.

Sclerotherapy

Sclerotherapy is the transcutaneous injection of a substance into the malformation, which causes endothelial destruction and thrombosis. Indications for sclerotherapy include a well-localized AVM, occlusion of veins draining the AVM, and an AVM that cannot be accessed transarterially, usually because previous embolization has occluded the feeding arteries.⁵ Sclerotherapy of an AVM is riskier than treatment of a slow-flow lesion, because the sclerosant is more likely to escape into the systemic circulation.

Resection

Resection of an AVM has a lower recurrence rate than embolization.⁶⁵ Indications include a well-localized lesion, correction of a focal deformity, or a symptomatic AVM that has failed embolization⁵ (Fig. 11-18). Extirpation and reconstruction of a large, diffuse AVM should be exercised with caution, because cure is rare and the recurrence rate is high, the resulting deformity is often

Fig. 11-18 Resection of AVM. **A**, This 39 year-old-woman had an ulcerated, bleeding, painful stage III AVM of the forehead and scalp since adolescence. **B**, Intraoperative view after preoperative embolization. **C**, Soft tissue defect after resection. **D** and **E**, The wound was closed using a split-thickness skin graft. **F**, Nine months postoperatively, the graft is concealed by hair.

worse than the appearance of the malformation, and resection can be associated with significant morbidity.⁵ When excision is planned, preoperative embolization will facilitate the procedure by minimizing blood loss. Excision should be carried out 24 to 72 hours after embolization, before recanalization restores blood flow to the lesion. Small, well-localized AVMs or those that cannot be accessed for embolization may be resected without preoperative embolization. Proximal feeding vessels to the AVM should never be ligated, because collateralization will stimulate enlargement, and access for future embolization will no longer be possible. Most defects can be reconstructed by advancing local skin flaps. Grafting ulcerated areas from the skin has a high failure rate, because the underlying tissue is ischemic. Excision with a regional flap transfer may be required. Free-flap reconstruction permits wide resection and closure of complicated defects.

VASCULAR MALFORMATION OVERGROWTH SYNDROMES

CLOVES Syndrome

Congenital lipomatosis, overgrowth, vascular malformations, epidermal nevi, and scoliosis/skeletal/spinal anomalies (CLOVES) is a condition that is caused by a somatic mutation in *PIK3CA*.⁵ Many of these patients previously were thought to have Proteus syndrome. Patients with CLOVES do not have cerebriform connective tissue nevi involving the hands and feet, and the condition is not significantly progressive. All individuals with CLOVES syndrome have a truncal lipomatous

mass, a slow-flow vascular malformation, and hand/foot anomalies. Other common features include paraspinal fast-flow malformations, linear epidermal nevus, and hemihypertrophy. MRI is obtained to determine whether the spinal cord is threatened by a lipomatous lesion or AVM. Children are at risk for developing Wilms' tumor and require screening.

Klippel-Trenaunay Syndrome

Klippel-Trenaunay syndrome (KTS) is a capillary-lymphatic-venous malformation of an extremity causing overgrowth.⁵ The condition almost always affects the lower limb. The contralateral foot or hand can be enlarged and exhibit macrodactyly. The venous component of KTS manifests as phlebectasia and abnormal drainage of the affected area. A large embryonic vein in the subcutaneous tissue known as the *marginal vein of Servelle* is isolated in the lateral calf/thigh and communicates with the deep venous system. Complications include thrombophlebitis and pulmonary embolism. The lymphatic abnormalities are usually macrocystic in the pelvis/thigh and microcystic in the abdominal wall, buttock, and distal limb. MRI is obtained to confirm the diagnosis and determine the extent of the disease. An important feature of KTS is that the tissues below the muscle fascia are affected by the malformation. Patients with KTS are not at increased risk for Wilms' tumor; thus screening is unnecessary. Because embryonal veins can connect to the deep venous system causing thromboembolism, these veins are removed in early childhood with sclerotherapy or endovascular laser.

Maffucci Syndrome

Maffucci syndrome is a nonhereditary disorder that is characterized by multiple enchondromas and soft tissue vascular lesions.⁵ The condition is caused by a somatic mutation in isocitrate dehydrogenase. The soft tissue vascular anomaly is called a *spindle cell hemangioma*, but this lesion is likely a reactive process in an underlying venous malformation. The spindle cell hemangioma/venous malformation can affect the hand, foot, arm, leg, trunk, and head/neck. The vascular lesions may cause overgrowth, pain from phlebothrombosis, and limitation of function. Enchondromas most commonly involve the hands. Problematic enchondromas are treated by curettage/excision and bone grafting. Chondrosarcomas are managed based on grade. Soft tissue spindle cell hemangioma/venous malformation can be treated with sclerotherapy and/or resection if symptomatic.

Parkes Weber Syndrome

Parkes Weber syndrome consists of a diffuse AVM of an extremity (usually the leg) causing soft tissue and/or bony overgrowth.⁵ A capillary malformation involves the skin of the affected limb. Parkes Weber syndrome can be sporadic or familial, resulting from a mutation in *RASA1*. Patients have subcutaneous and intramuscular microshunting and can develop congestive heart failure. Most children are observed until symptoms necessitate intervention. Embolization may reduce congestive heart failure, pain, or ulceration. Occasionally, amputation is necessary.

Proteus Syndrome

Proteus syndrome is a very rare sporadic overgrowth disorder caused by a somatic mutation in *AKT1*.⁵ The major features are:

- Progressive overgrowth of body parts (typically skeletal/limbs)
- Cerebriform connective tissue nevi (volar hands, plantar feet, chest)

- Epidermal nevi
- Vascular malformations
- Adipose overgrowth
- Cerebral anomalies
- Ophthalmologic findings
- Cystic lung disease
- Renal/urologic anomalies
- Bone disorders (skull hyperostoses, megaspondylodysplasia)

The significant progression of the disease and the cerebriform connective tissue nevus are pathognomonic for Proteus syndrome. There is a 20% mortality rate among affected individuals from venous thrombosis/pulmonary embolism, cystic lung disease, and neoplasms.

Sturge-Weber Syndrome

Sturge-Weber syndrome is defined by a capillary malformation in the V₁ trigeminal nerve distribution with ocular abnormalities (glaucoma, choroidal vascular anomalies) and/or a leptomeningeal vascular malformation.⁵ Patients also commonly have soft tissue and/or bony overgrowth.⁵⁸ Extensive pial vascular lesions may cause refractory seizures, hemiplegia, and/or delayed cognitive development. Patients also often have extracraniofacial capillary malformations. Any child with a capillary malformation in an upper trigeminal nerve distribution should be screened for Sturge-Weber syndrome. MRI is obtained to rule out leptomeningeal vascular lesions. Patients undergo an ophthalmologic evaluation to assess for choroidal anomalies and glaucoma.

KEY POINTS

- Vascular anomalies are common and affect both children and adults.
- The field of vascular anomalies is confusing, because numerous types of vascular anomalies exist, different lesions have a similar appearance, and the terminology can be confusing.
- Accurate diagnosis of the lesion must be ascertained before treating the lesion.
- Patients with problematic vascular anomalies are best managed in an interdisciplinary vascular anomalies center.
- Vascular malformations are managed by observation, laser, sclerotherapy, embolization, or resection; pharmacotherapy is not available.

Pediatric Tissue Expansion

Bruce S. Bauer • Sara R. Dickie

issue deficiency is the underlying problem encountered in the care of many congenital and acquired deformities in the pediatric population. With deficiencies in both the soft tissue and skeleton, no single treatment modality can provide all the answers. Experience with a broad spectrum of difficult pediatric reconstructive problems has demonstrated that *tissue expansion* (TE), either as a primary modality or as an adjunct to other reconstructive techniques, provides a reliable mechanism for replacing the missing soft tissues. When treating large skin lesions or scars, TE provides like-quality and like-texture skin to replace the tissue to be excised. When treating craniofacial deformities (either congenital or acquired), TE can provide added tissue to cover the reconstructed skeleton and replace skin deficiencies. TE also provides a means of moving composite tissues from distant sites to provide skin coverage and soft tissue fill after resection of tumors and to reconstruct contour defects where both the size of the donor area and closure of the donor defect present possible limitations.

BACKGROUND

Although the genesis of modern day TE is credited to innovators such as Radovan¹ and Austad and Rose,² the technique takes some of its roots from early lessons in distraction osteogenesis. Bone traction with either internal or external devices at the turn of the twentieth century led to the concept that mechanical stress could lengthen tissue.^{3,4} Putti⁵ extrapolated these ideas from bone to surrounding soft tissue by placing constant tension on a composite tissue to obtain soft tissue lengthening. In the 1950s, Neumann⁶ became the first surgeon to use an expansile implant, when he used a latex balloon to enlarge periauricular skin for a traumatic ear deformity. Despite these early efforts, it was not until 20 years after Neumann's report that TE was revisited. Charles Radovan,¹ a resident at Georgetown, reintroduced the concept of expansion when he inserted a contemporary device with an internally placed port. Shortly thereafter, Eric Austad² produced a

self-inflating device. In 1982 the first National Tissue Expansion Symposium was sponsored by the Plastic Surgery Educational Foundation, marking the recognition of a new advance in reconstructive surgery. Since that time expansion has been applied to many reconstructive problems, with applications in both regional expansion and expansion at distant sites for subsequent graft and flap transfer. A better understanding of expansion has led to many flap design modifications, thereby increasing its worth as a reconstructive option.⁷

PHYSIOLOGY

Skin is a unique substance composed of a viscoelastic cellular and extracellular matrix. When a constant mechanical stress is applied to skin over time, two phenomena have been observed: *mechanical creep* and *biologic creep*. Mechanical creep is based on morphologic changes that occur on a cellular level in response to the applied stress—the cell is stretched. Disruption of gap junctions and increased tissue surface area also result in cell proliferation (biologic creep). Growth of the tissue by cell proliferation restores resting tension of the tissue to baseline.⁸ Histologically, the early work of Sasaki⁹ and his colleagues pointed to a proliferative response of the epidermis with concurrent thinning of the dermis and alignment of collagen fibrils. In humans, these effects are maximized at 6 to 12 weeks after expansion.¹⁰ On a molecular level, a panoply of growth factors, cytokines, hormones, adhesion molecules, cytoskeletal elements, and signal transduction proteins is induced in response to expansion, confirming that TE is a dynamic process.¹¹

One of the features that makes an expanded flap so reliable is its improved vascularity. Many studies have demonstrated that the vascularity of an expanded flap is superior to its nonexpanded counterpart in both the number and caliber of vessels.¹² Moreover, angiogenic factors, such as vascular endothelial growth factor, are expressed on the surface of expanded tissue at a significantly higher level than on nonexpanded controls.¹³ This augmentation of blood flow is attributable to the capsule that forms around the expandable prosthesis. Because expanded flaps and delayed flaps are similar in vessel caliber, TE has been regarded as a form of the delay phenomenon. An expanded flap, therefore, is a delayed flap.

KEY CONSIDERATIONS

Successful expansion, regardless of the indication, begins with careful case selection. The surgeon must have an understanding of the potential problems and how to avoid them, and between the surgeon and his or her nursing staff, the parents and patients (when old enough) must be brought to a thorough understanding of the expansion process and its potential complications.

The choice of expander, the incision for placement, and the expansion routine may vary, depending on the site of expansion and the underlying defect being treated. Experience has demonstrated that a higher rate of complications in nonnevus cases may require variation in technique. Also, a surgeon should always consider whether techniques other than expansion are more suitable for reconstruction in a particular case.

Tissue Expander Design

Several types of tissue expanders exist, based on shape, size, and type of filling valve. Expanders can be standard, customized, anatomic to the donor site (breast), or differential in fill volume to provide tissue tapering. They follow three basic shape patterns: round, rectangular, and crescent (and croissant, a variant of crescent). The more commonly used are the round and rectangular types. Crescent (and croissant) prostheses, developed to minimize dog-ears at the donor site, have

Fig. 12-1 Rectangular tissue expander with a thicker base plate, tubing, and remote filling port.

fallen out of favor, because the added tissue gained with rectangular expanders may increase the potential choices for flap design (such as transposition flaps). Outside of expansion for breast reconstruction, we now use rectangular expanders in all cases.

Expander volumes have a wide range and vary according to the anatomic site. Round expanders of 100 to 2000 cc and rectangular expanders of 70 to 1200 cc are available (smaller and larger custom expanders are available to meet uncommon anatomic requirements). Saline solution is delivered in a controlled fashion through the valve port, which is either integrated into the prosthesis or connected to the device by a customized length of silicone tubing (Fig. 12-1). An integrated system offers the advantage of undermining a single pocket for expander placement, but it also places the implant at risk of perforation by a misplaced needle. On the other hand, internal remote ports remove the danger of perforating the prosthesis itself but introduce the potential complications of flipping over, tube obstruction, and migration. To avoid these complications, the port pocket undermining should be minimal, the port should be placed over firm supporting tissue, and, if necessary, the port position should be fixed with sutures (see Fig. 12-4, *E*). In more mobile areas, such as an extremity, the risk of the port flipping over can be minimized by using a larger (standard) port rather than a “mini” port. The port size does not affect the amount of fill that can or should be provided to various sizes of tissue expanders.

A variety of expanders are available with designs aimed at keeping the profile of the expander low. In our experience, several of these designs gain low profile at the expense of increased firmness of the expander envelope. We currently use an expander with slightly firm backing that allows the redundant envelope to be folded beneath the base when first placed. This avoids folds and firm points that may compromise overlying skin. As the expander increases in size, the redundant envelope gradually unfolds beneath the enlarging flap.

Expander Placement and Expansion Routine

Consideration for incisions, expander placement, flap movement in relation to the defect, and postoperative scars takes appreciable preoperative planning and discussion with the patient and family. The surgeon must match color, texture, and contour of the recipient site to the donor site to maximize aesthetic and functional outcome. The donor tissue must be free of infection, scars (or have stable scars), or trauma to prevent implant failure or extrusion. In most nevus cases an expander is placed through an incision within the border of the lesion. In other cases (such as

unstable scars, vascular tumors, and craniofacial deformities), incisions are planned outside the border of the defect or occasionally at a distant site.

The resulting skin flaps must be handled gently; rough or aggressive retraction or collision of the flaps with instruments can lead to skin-edge necrosis. The pocket is dissected to allow placement of the largest expander indicated, creating the pocket approximately 1 cm larger than the expander in all directions. Typically an internal remote port is used, with placement over a region of firm skeletal support (for example, the preauricular region, cranial vault, rib or iliac crest, or anterior thigh for trunk/abdominal TE) to ease outpatient filling. Partial fill of the expander (usually to 10% to 20% of its listed volume) ensures that the expander is properly positioned and without firm surface folds. Closed suction drains also serve to control potential dead space from wide undermining. In most cases the expander pocket incisions are closed in watertight fashion with judicious placement of 4-0 clear nylon buried intradermal sutures, followed by 4-0 Prolene running continuous suture. Skin flaps are dressed nonadherently (bacitracin, Xeroform gauze), followed by soft padding (fluffs).

Although the family receives thorough preoperative education about the tissue expander, parents are often more comfortable if their child remains in the hospital for observation for the first postoperative night. Patients may also be monitored overnight for potential compromise or hematoma formation and to manage pain control.

Serial injections are started 7 to 10 days after insertion of the expander, if the skin flaps are in excellent condition. After one or two postoperative visits for drain removal (postoperative days 3 to 10) and education (greatly aided by preoperative teaching), most pediatric patients are able to begin a home expansion protocol directed by parents or guardians. One study demonstrated that home expansion is as safe as office expansion, and the successful outcome rates are nearly equivalent (96% for office expansion versus 90% for home).¹⁴ Expansion should render the skin tense, but it should not be painful to the patient or compromise the skin. Either condition suggests excessive filling, which must be corrected immediately.

In our practice, families are given the option of home or office expansion. When the option for home expansion was introduced nearly 30 years ago, approximately 20% chose to expand at home. Today our practice manages nearly 80% of our patients with home expansion. Families typically proceed with a well-established expansion protocol for 8 to 12 weeks before the expander is removed and reconstruction can be performed. Parents record progress with digital images and transmit these by email correspondence during the expansion. The parents are also provided with a printed card to record the schedule and amount of saline solution injected throughout the expansion process.

The Internet has provided a powerful tool for following patients, even at a distance. It also gives families a measure of comfort, because they are never far from advice and support. It is important to obtain consent from parents and patients before communicating by email and using this for image transmission. Physicians should ensure the presence of data encryption systems and password-protected accounts with practice management, hospital administration, parents, and patients to preserve patient privacy and remain in compliance with the Health Insurance Portability and Accountability Act (HIPAA).

Although each case varies, depending on the underlying anatomy and reconstructive problem, a rough guideline for typical injection amounts by site is:

- Scalp: 20 to 50 cc
- Cheek: 5 to 10 cc
- Forehead or adjacent neck: 10 to 20 cc
- Trunk: 50 to 100 cc

TE in the extremities varies based on the size of the expander, the site on the extremity, and the age of the patient. Expanders are usually injected with saline solution once per week, and the overall amount is monitored closely so that midway through the process, the frequency of injections may be increased to every fourth or fifth day if it appears that the target expander removal date will be significantly delayed. If the desired volume is reached earlier than expected, an effort is made to move up the excision and reconstruction schedule.

Antibiotics

A broad-spectrum antibiotic is initiated when anesthesia is induced and is continued for 7 to 10 days postoperatively, depending on when the drain is removed. Previous studies support our own experience that ear infections and various viral infections may seed the expander site, resulting in an infection. By maintaining a low threshold for placing the patient back on a broad-spectrum antibiotic in the presence of an upper respiratory infection, ear drainage, or unexplained fever, most infections can be prevented or incipient infections squelched before the potential loss of the expander. Myringotomy and tube placement should be considered in patients with chronic ear infections before undertaking expander placement, balancing the risk of infection and expander loss against the risk of the myringotomy and tubes. The latter should especially be considered in a child who will undergo multiple rounds of expansion. With multiple expanders, infection leading to complications in one expander may be addressed without the need to remove other expanders. This is particularly important when the problem is encountered early in the course of expansion.

Expanded Flap Design

The design of an expanded flap is a significant undertaking. Although the early dogma of TE emphasized expansion as a means of generating large advancement flaps only, experience has demonstrated that expanded transposition and rotation flaps may frequently be preferable for many reconstructions.^{7,15} Clearly, the increased vascular supply of the expanded flap places little limitation on the ingenuity of the surgeon for designing flaps unique to the recipient defect. Although requiring more planning and forethought, transposition of the flap provides greater versatility in flap design and range.⁷ What differentiates an expanded transposition flap from an unexpanded one is that when the flap base is expanded, the flap not only transposes, but it also advances because of the tissue gained in the area of the pedicle. This allows significant movement of the flap (particularly in an axial direction) and therefore an improved ability to cover large surfaces with each expansion.

REGIONAL CONSIDERATIONS

We will discuss the considerations needed for successful pediatric TE in each body region based on nearly 35 years of experience with more than 3500 tissue expanders.

Scalp

There are three general indications for pediatric scalp reconstruction with TE: to surgically correct large congenital nevi, to correct scar and skin graft alopecia, and as an adjunct to craniofacial reconstruction.^{7,16} Despite previous concerns that expansion may affect cranial vault morphology, an early examination by CT analysis of more than 20 infants undergoing scalp expansion found no distortion or other untoward effects on cranial sutures.¹⁶ We have not seen a case of permanent

deformation of the skull in an expander patient in all our years of using TE. Although cranial molding may appear, this usually corrects itself within 1 to 3 months.

We delay placement of expanders in babies with significant positional plagiocephaly until the greater part of cranial remodeling has occurred. We typically place expanders for treating large and giant nevi at 6 months of age. Expansion for the treatment of extensive areas of cutis aplasia is typically delayed until the patient is at least 1 year of age, when the scar tissue is more stable.

Fig. 12-2 illustrates the use of TE with reconstruction for cutis aplasia. It also demonstrates that excessive scoring or excision of the thickened capsule in the area of the flap pedicle may result in possible flap compromise. Expanders are placed to allow maximal expansion of the areas of normal scalp that will provide the optimal hair orientation after the reconstruction, and the next round of expansion is always delayed at least 4 months. Expanders are never placed immediately at the time of nevus excision and flap repair. At subsequent rounds of expansion, a larger expander can be placed to distribute the expansile forces evenly over the hair follicles.¹⁶

As previous studies have shown, TE does not induce proliferation of hair follicles, but it can more than double the size of the scalp without a visible decrease in hair density. Fig. 12-3 demonstrates TE for the reconstruction of postirradiation alopecia. Expansion is effective but may be slow, and exposure of the expander because of poor healing may limit complete expansion but not compromise the final result. For expander placement, pocket dissection is performed subgaleally (and subfrontalis when combined with forehead expansion). Dissection is typically easiest with a graduated series of malleable retractors and pediatric urethral sounds to spread open the pocket with limited trauma to the overlying flap. Flaps are designed with consideration given to the major blood supplies to the scalp (that is, the superficial temporal, postauricular, occipital arteries, and contributions from the supraorbital vessels). Port placement in the preauricular region has produced the least migration.

Capsular tissue commonly creates a thick ridge of fibrous tissue along the cranium while the expander is in place. When the expander is removed and the flap advanced, the ridge is often visible and palpable, which can be distressing to the patient and parents. On removal of the expander, any remaining fibrous tissue will resorb and flatten, with the dissolution of the capsule in

Fig. 12-2 A and B, This 2-year-old girl had extensive cutis aplasia of the scalp.

Fig. 12-2, cont'd **C**, Three expanders were placed for 12 weeks of expansion (340 cc right, 250 cc left, and 70 cc occiput, with an external port for the occipital expander because of the limited placement site). **D**, During resection, an overzealous backcut of a thick capsule resulted in partial loss of the right-sided flap. A second expansion was performed 1 year later, resulting in excellent coverage. **E-G**, The patient is seen 6 years after reconstruction.

6 to 8 weeks. Although it may be tempting to excise this tissue to smooth the surface, it should be stressed that the capsular ridge contains a valuable vascular supply to the flap. Along the pedicle or trailing side of the flap, the capsular ridge should not be excised; doing so will lead to flap compromise. Similarly, we advocate against scoring of the capsule to gain extra length, because this will also have a negative impact on the vascularity and venous drainage. On the leading edge of the flap to be transposed, the capsular ridge can be sharply dissected from the skull to aid in flap inset and advancement.

Second to the breast, the scalp is likely the most frequently expanded region and the area with which most surgeons are familiar. The ability to reconstruct areas of scar alopecia, resect and reconstruct large scalp lesions, and replace defects with hair-bearing scalp makes expansion the reconstructive option of choice for many patients.

One technique that has proved valuable for complex reconstructive cases, particularly with scar alopecia (but equally valuable for scars, wounds, or defects at sites other than the scalp) when

Fig. 12-3 A and B, This 13-year-old girl was treated after a craniotomy for resection of a brain tumor with irradiation, chemotherapy, and stem cell rescue, and she presented with postirradiation alopecia of the right scalp. Two 500 cc expanders were placed in the frontoparietal and occipital scalp. C, Midway through expansion. D, Three weeks before the planned reconstruction, the frontal expander was exposed. The expander was removed, and the flap was partially advanced. E, Expansion was completed in the occipital region, allowing excision of the alopecia and reconstruction of the hairline. F and G, One month after surgery.

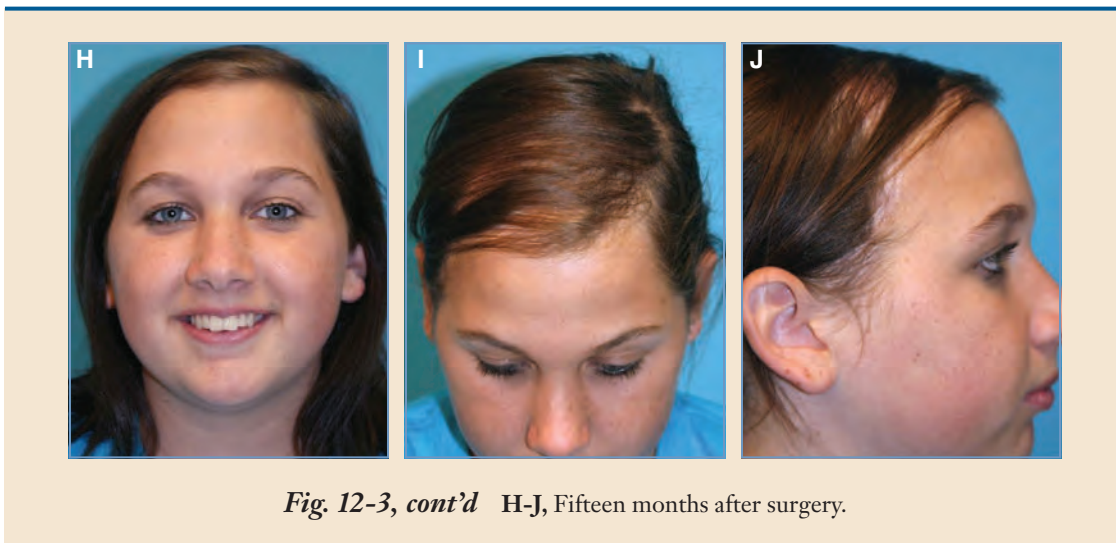

Fig. 12-3, cont'd H-J, Fifteen months after surgery.

there is minimal available donor tissue is “in situ” serial expansion. If serial expansion is required to fully reconstruct a defect, yet the scar tissue is too tenuous to allow adequate healing (after the first flap advancement) for performing subsequent expansions without risk of expander extrusion, the initial expander can be fully expanded and then switched for a larger expander in the same pocket. The flap can then be further expanded before the first flap advancement is performed. This swap of expanders can be carried out through a minimal incision, and the new expander can be connected to the same injection port. Generally, the second expander can be expanded to the same volume as the one being replaced at the time of the switch. Because a significantly larger flap has been created, it can safely move beyond the region of unstable scar.

The use of expanded transposition flaps rather than simple advancement flaps has greatly reduced the number of serial expansions required and has resulted in improved reconstruction of hair direction and hairline (particularly the temporal hairline). Fig. 12-4 illustrates expansion of an occipital transposition flap and hemiforehead flap for reconstruction of the parietal scalp, temporal hairline, and forehead in a patient with a giant nevus. In hemiscalp or near-hemiscalp reconstruction for a nevus or scar alopecia, temporal hairline reconstruction is best accomplished with a large transposition flap from the occipital region.⁷ In the young boy with a large facial nevus shown in Fig. 12-5, the design and staging of forehead, nasal, cheek, and scalp reconstruction are demonstrated, with staged forehead, scalp, and neck flaps.

Forehead

Expanded flap reconstruction of the forehead provides some of the most challenging cases because of its potential morbidity and its potential to disfigure the upper facial structures such as the brow. The surgeon must respect the aesthetic subunit to avoid late complications. A retrospective review of our early cases revealed a 24% aesthetic complication rate with forehead TE, including brow asymmetry, brow ptosis, altered hair direction, and anterior hairline asymmetry¹⁵ (see Figs. 12-4 and 12-5).

Fig. 12-4 A and B, The patient is shown at initial presentation. C and D, Starting when he was 6 months of age, two 250 cc expanders were placed under the normal forehead skin and the occipital scalp behind the nevus. E, Before first-stage partial excision of the nevus and removal of expanders. The buried port can be seen below the nevus. F and G, Shown immediately postoperatively, following the tenet: “Don’t overextend—reexpand.”

Fig. 12-4, cont'd H and I, Four months after the first stage. J, In the second round of expansion, two 250 cc expanders were placed under the previously expanded forehead and parietal scalp. K and L, The patient is shown 1 week after the second stage with completion of the excision and expander removal. M, The first day of preschool, 18 months after scar revision for the brow.

Fig. 12-5 This patient presented with a large facial nevus. Staged forehead, scalp, and neck flaps were planned. **A**, When he was 6 months of age, a 250 cc expander was placed in the hemiforehead and under the occipital scalp for 12 weeks of expansion. **B** and **C**, Four months after first-stage reconstruction of the nose and part of the forehead, the temporal hairline has been put into correct position, abutting the facial nevus that will be resected in the coming surgeries. **D**, The second round of expansion was started 6 months after the first resection and focused on the remaining forehead and the cheek. A 250 cc expander was placed under the previously expanded forehead flap, and a 70 cc expander was placed in the lower cheek to reconstruct the cheek and lower temporal hairline; expansion continued over 10 weeks. (The cheek can also be done with a 250 cc expander in the neck of a child, depending on the size of the area needing reconstruction.) **E** and **F**, Four months after second-stage reconstruction of the forehead and cheek. **G**, Third and final expansion of the forehead flap with another 250 cc expander, which was placed 6 months after the previous surgery and expanded for 10 weeks. **H**, Immediately after completion, excision of the forehead nevus.

Fig. 12-5, cont'd I, Four months after the final expander stage. J-L, The boy is seen 18 months after final expansion at age $3\frac{1}{2}$. A scar revision of the brow had been performed in the interim.

Most of these complications are corrected with minor secondary procedures, but over the years certain guiding principles have been developed to minimize these late complications:

- Bilateral expansion of normal forehead tissue is often successful for midforehead lesions. Although completion of the aesthetic single unit forehead reconstruction should be considered if there is a wider area of normal forehead skin available to expand for a central defect.
- As with the scalp, serial expansion of the forehead is often required for hemiforehead reconstruction. The surgeon should remember: “Don’t overextend the flap; reexpand it.”
- Supraorbital and temporal lesions and scars are managed with a combined advancement and transposition of expanded normal skin medial to the lesion or defect.
- With minimal involvement of the temporal region, parietal expanded scalp can be advanced to reconstitute the hairline.
- When advancing and transposing the forehead flap, it is necessary to set the position of the brows as a primary step. We use three or four judiciously placed 4-0 clear nylon sutures to tack the deep brow tissue to the periosteum along the superior orbital rim. Paying close attention to obtaining symmetry will help reduce the need for secondary procedures. This also helps to prevent distortion of the contralateral brow.

- It is easier to elevate a brow later than to bring an elevated brow down. In cases of brow elevation, the abnormal brow can be returned to its preoperative position by interposing non-hair-bearing forehead skin. However, it does not work to simply expand the adjacent forehead skin to reorient the brow, because this tissue will recoil postoperatively. There must be some transposition of the tissues and resuspension of the brow itself to prevent relapse of the defect.

Opinions vary regarding the efficacy of expanding forehead flaps for nasal reconstruction with complex congenital nasal defects and acquired loss of nasal tissues. Although the donor wound on the forehead can be left to contract quite successfully in adults, a wide paramedian scar can be particularly disfiguring in a child. This scar can be minimized with additional tissue gained by TE (Fig. 12-6; see Fig. 12-5). An expanded forehead can also be used for upper eyelid reconstruction by transposing a flap inferior to the eyebrow. Although the pretarsal eyelid is best reconstructed with a skin graft, the preorbital eyelid tissue is often thicker and benefits from the thin layer of subcutaneous fat that is brought with an expanded forehead flap in this area (Fig. 12-7).

Fig. 12-6 Although opinions vary on the need for expansion of a forehead flap for nasal reconstruction, expansion allows tension-free closure of the donor site in a child. **A** and **B**, This child was born with total agenesis of the right side of the nose and hypoplasia of all nasal structures (including minimal choana on the left, which was associated with a midline cleft lip and multiple other congenital anomalies). She is shown in infancy before any facial surgery and at 3 years of age after an initial attempt at reconstruction without adequate skeletal support or reconstruction of the nasal airway.

Fig. 12-6, cont'd C-E, When she was 5 years of age, a 250 cc expander was used to expand the forehead, and first-stage reconstruction was performed on the left nasal airway with bone resection and flap lining. F and G, Expanded flap reconstruction over combined rib and cartilage grafts with completion of the left nasal airway reconstruction and creation of a false nostril on the right side. H-J, The result is seen 11 years postoperatively when the patient was age 16. She had not undergone any further surgery.

Fig. 12-7 Reconstruction of the upper eyelid and nose can be completed with expanded forehead skin for an optimal color and texture match. **A**, This patient presented at 6 months of age with an isolated, complex nevus of the left upper lid, brow, and nasojugal area. **B**, A 250 cc expander was placed in the ipsilateral forehead and was expanded for 8 weeks. **C**, The child is shown 8 months after expanded forehead flap reconstruction of the upper eyelid and nasojugal region with an island scalp flap for the eyebrow. **D**, The patient is seen at 2 years of age, 3 months after scar revision and contouring of the flaps around the canthal region, plus microhair grafting for the brow. **E**, The boy is seen at 5 years of age without further surgery.

Face and Neck

To achieve an optimal aesthetic and functional result in the facial and cervical regions, the surgeon must adhere to a subunit principle.¹⁷ This principle dictates that incisions be placed so that the scar is hidden in a natural crease, such as the nasolabial fold. Analogous to upper facial structures (such as the brow and the eyelid), undue tension on the lower face can disfigure critical structures, leading to lower lid ectropion, lip drooping, and oral incompetence. Advancement of cervical skin flaps cephalad to the cervicomandibular angle bears an increased risk of late complications. Neale et al¹⁸ reported a 10% lower rate of eyelid ectropion and a less than 10% lower rate of lip deformity in this context. The use of expanded transposition and rotation flaps from the lateral cheek, neck, and postauricular area minimizes the risk of these problems.^{7,15} Early in our practice, we based neck and cheek flaps medially, with the transposition occurring along the preauricular region and the zygoma, as a Mustardé-type lateral cheek flap. However, this design required frequent revision for ectropion because of the lack of supporting tissue for the flap. In addition, this design often required repeat expansion to complete the aesthetic unit reconstruc-

Fig. 12-8 A, This patient was 16 years old when she presented to our practice with an intermediate-sized congenital pigmented nevus. B, A 70 cc expander was placed in the cheek adjacent to the nevus, and she underwent 8 weeks of expansion. C and D, The girl is seen 1 month after surgery, with scars settled nicely along the borders of facial subunits, especially along the nasolabial and mental creases.

tion. In our current practice, the cheek, lower lid, and nasojugal lesions are treated with an expanded flap based laterally; transposition takes place from the submental neck, with incision lines placed along the nasojugal, nasolabial, and mental creases (Fig 12-8.) Over time, we have noted that by securing the expanded capsule along the periosteum of the piriform process and the medial and lateral orbit, the flaps are well suspended. Fig. 12-9 shows the use of the capsule to aid in suspension of the flap by anchoring it to the periosteum of the orbital rim and piriform process. Judicious flap design, the use of multiple expanders, and overexpansion are recommended to further minimize complications.¹⁸

Expanded full-thickness skin grafts can also achieve better functional and aesthetic results than split-thickness grafts; using the benefits of expansion will virtually eliminate graft size as a limitation for choosing this reconstructive modality.¹⁹ Preexpansion of donor sites allows larger full-thickness skin grafts for areas such as the periorbital or dorsal aspects of the hands and feet. Part of the expansion provides for the graft tissue or free flap, with the remainder providing tissue for primary closure of the donor site. The neck above the clavicle is the ideal donor site for grafts to be placed on the face (for example, a single expanded full-thickness skin graft to the entire forehead subunit) because of the excellent color and texture match. These expanded full-thickness grafts have all the characteristics of their unexpanded counterparts with regard to

Fig. 12-9 A, This patient was 1 year old when he presented with a variegated, large congenital pigmented nevus of the entire cheek subunit. B, A 70 cc expander was placed into the lower cheek and neck, and he underwent 10 weeks of serial expansion. C-F, Operative steps show the incisional planning. By placing sequential incisions into the flap at the point where the nasolabial crease meets the mental crease, the medial aspect of this flap transposes into the nasojugal region and extends the tip toward the medial orbit for suspension. The capsule is shown extending all the way to the edge of the flap. This will be used to secure the flap to the periosteum.

Fig. 12-9, cont'd **G-I**, Using a bovie or sharp scissors, a small area of periosteum is exposed at the key anchor sites, and 4-0 clear nylon sutures are placed to suspend the flap. **J**, The patient is seen 3 years after surgery at 4 years of age. The flap is well suspended without ectropion.

durability, texture, minimal contraction, and growth. Fig. 12-10 illustrates the use of expansion to allow harvest of a full-thickness skin graft to cover the eyelids and periorbital area in a single unit from an expanded supraclavicular donor site. It also demonstrates the use of a portion of the expanded forehead flap to cover the nasal dorsum after nevus excision. Although in the past we used a single-piece expanded full-thickness skin graft for coverage of the periorbital region (including both eyelids), today we prefer to use one of two postauricular grafts with a full-thickness skin graft from the groin to the postauricular donor site.

Preexpansion is also useful for distant pedicled flaps (such as the supraclavicular artery flap to the lower face) and free tissue transfer for similar reasons as discussed earlier. The delay principle can enlarge the angiosome territory that can be captured on a single pedicle. Free flap donor-site morbidity is also an important consideration. Grafting of donor sites suffers the same color and contour mismatch as if one were grafting a primary defect. Although these sites are often on the trunk or lower limbs, they are no less important when it comes to considering the lifelong impact that such a deformity can have on an individual's functional status and self-image. Free flap harvest from distant sites can reconstruct complete cheek or forehead aesthetic units when regional tissue is not available to expand for flap tissue. Fig. 12-11 illustrates expansion of a distant flap for

Fig. 12-11 A and B, This child was born with a congenital giant pigmented nevus involving the entire forehead, midfrontal scalp, brows, and nasal dorsum. Biopsies at 5 months of age demonstrated infiltration of the nevus through the underlying frontalis muscle, contraindicating expanded full-thickness coverage of the muscle and forehead aesthetic unit. When she was 18 months of age, the forehead nevus was excised after expansion of the adjacent normal scalp, leaving the forehead, brows, and nose. C, At 2½ years of age a 500 cc expander was placed in the right back, adjacent to a planned free scapular-parascapular flap to allow primary closure of the donor site, with a delay carried out 1 week before transfer. D and E, The flap was elevated and transferred with a vein graft to the superficial temporal artery, allowing excision of the nevus, except for a segment left for each eyebrow. F, One week after inset of the flap and before subsequent contouring of the nasal area. G, Six months postoperatively. H-J, The patient is seen 9 months after resection of the remaining nasal nevus and contouring of the flap.

free tissue transfer to reconstruct the entire forehead aesthetic unit and a portion of the nasal dorsum. Free flaps are also valuable for large defects involving the extremities (discussed later). In all cases, the expansion is carried out adjacent to the planned free flap and away from the pedicle.

Trunk

Beyond its obvious usefulness for treating deformities of the breast, TE has multiple applications on the trunk for treating giant nevi, vascular malformations, and contour defects.²⁰ It is also a useful adjunct to other procedures for closing congenital or acquired chest, abdominal, and back defects. Not unexpectedly, the lower abdomen is perhaps the most easily expanded site and can be used when excising adjacent lesions, as donor tissue for expanded pedicled flaps or flaps for free tissue transfer, such as for expanded transverse rectus abdominis myocutaneous (TRAM) flaps, where expansion is carried out to aid in donor-site closure, or expanded upper abdominal flaps to help close a large deep inferior epigastric perforator flap defect (Fig. 12-12), and as a donor site

Fig. 12-12 A combined regional expansion on the extremity and expansion of the TRAM flap for microvascular transfer. **A**, The patient presented at 8 years of age with a mixed lymphaticovenous malformation of the thigh and lateral knee associated with chronic drainage, pain, and limitation of activity. The lesion was too extensive to allow excision and reconstruction with regional expansion alone. However, regional expansion was planned to reduce the overall size of the expanded free TRAM flap that was planned for reconstruction of the greater portion of the defect. **B**, Expanders of 500 cc each were placed at both sites and expanded over 11 weeks. The abdominal expander was placed adjacent to the flap to allow harvest of a large flap with tension-free closure of the donor site. **C-E**, Resection and repair with advancement of the adjacent expanded flap and inset of the free TRAM flap.

Fig. 12-12, cont'd F and G, The patient is seen 3 years after resection and reconstruction, before minor contouring of the flap with liposuction.

for large expanded full-thickness grafts.¹⁹ Expansion on the anterior trunk is limited in females by the need to avoid potential distortion of the breasts. For males, temporary movement of the nipple-areola complex can be corrected at the completion of the flap reconstruction by grafting it back in the appropriate location. For the trunk, keeping in mind the need to place the injection port over firm skeletal structures, the injection ports are frequently placed in the anterior thigh or, less frequently, over the anterior ribs.

Expansion on the posterior trunk has become the modality of choice for treating many large and giant nevi of the back and buttock area. Whether advancing skin caudally or cephalad, serial expansion is frequently required to excise extensive lesions. Expansion can begin as early as 6 months of age for treating large and giant nevi in children and is clearly easier in the earlier years than later in life.

For patients with lesions that are circumferential or that involve both an anterior and posterior component, we stage the expansions, preferring to begin on the back and then placing front expanders in a second round or third round. Typically, for a large nevus on the back, flanks, and abdomen, two expanders are placed in the upper back/chest/flank, wrapping down along the upper margin of the nevus and positioned just off midline medially. When expanded, these flaps provide large transposition flaps and the largest degree of flap movement. These are then expanded in the next round to move further caudal as well as laterally. Today it is not uncommon to have expanders in place on both the anterior and posterior trunk.

The lower back may be expanded to develop large transposition flaps to cover the buttock, and the lower abdomen can be expanded to create similar flaps for coverage of the anterior thigh. Again, the use of large expanded transposition flaps has allowed excision and reconstruction of giant nevi with fewer procedures and more aesthetic and functional positioning of the final scars^{7,21} (Fig. 12-13). The same principle can be carried out by moving the tissue from an uninvolved hemiabdomen across the abdomen and lower chest when the normal tissue is unilaterally placed and the normal tissue in the lower chest cannot be expanded without risk of distorting the breast. Expansion of the lateral abdomen, flank, and/or back is also used commonly to develop large expanded pedicled flaps for reconstruction of large nevi on the upper extremity.

Fig. 12-13 This young child underwent early excision of most of his giant nevus at 2 months of age and reconstruction with a thin-meshed, split-thickness skin graft and Integra. However, graft take was poor, and there was severe hypertrophic scarring. TE was used as a means of secondary reconstruction for treating the scar deformity. **A**, At the time of his presentation at 2 years of age, the patient had significant limitation of movement, severe pruritus, and pain associated with the scarring. Staged expansion of the back and shoulders was planned to excise the graft and scar tissue. **B**, Expansion of the two 750 cc expanders in the lower back and the 250 cc expander in the right shoulder is nearly complete. They were placed at 2½ years of age and expanded over 11 weeks. **C**, The result is seen immediately after initial partial excision and flap reconstruction. **D**, Two months postoperatively. **E**, At 3½ years of age, 6 months after removal of a second set of expanders and further resection of graft and scar, and before placement of a third set of expanders. **F**, Early in the third serial expansion. Two 750 cc expanders were used in the upper right and lower left back, and a 250 cc expander was used in the left shoulder.

Fig. 12-13, cont'd **G**, After 10 weeks of expansion. **H**, Result 5 months after completion of the excision and reconstruction. **I** and **J**, The patient is seen at age 5, 1 year after his final surgery.

Expansion has been used as an adjunct for treating secondary problems associated with myelomeningocele more commonly than for early repair. Expanded cutaneous and fasciocutaneous flaps can provide more stable coverage for planned spinal fusion and for salvaging exposed hardware when complications arise.

Congenital Breast Anomalies

Expanders and expandable implants have found roles in postmastectomy breast reconstruction and habilitation of congenital breast anomalies.²⁰ Much of this is covered in Chapter 60, but a few comments seem pertinent here with regard to reconstruction for congenital breast anomalies.

Expanders can be helpful as “spacers” when correcting congenital breast anomalies. Requests for breast habilitation come from patients with breast agenesis associated with Poland’s syndrome, idiopathic unilateral breast hypoplasia, and iatrogenic breast asymmetry caused by juvenile

breast bud damage. Traditional wisdom has been to wait for maturity before correcting breast asymmetries. This strategy ensures that the surgeon knows what needs to be matched on the opposite side. Although this solution may have been acceptable at one time, today's young adolescent female has problems with changing in locker rooms, participating in sports activities, and wearing fashionable clothing. Questions of developing self-esteem, body image, and sexual identity further compound the issue of waiting. Expanders can function as an intermediate solution.

Many young women are happy with breast volume symmetry so that they appear normal in a bra. With this goal in mind, an expander can be placed as early as the opposite breast begins to develop and can be expanded over time. Aesthetic surgeons also use this method to adjust breast size over time.²⁰ The use of either an expander or an expandable implant in these patients may constitute an off-label use for these devices. Expanders are not constructed for prolonged use (that is, over the 6 to 8 years of breast development). Adjustable permanent implants are designed for longer-term use but are supposed to have their ports removed promptly after complete fill to prevent implant deflation. A discussion of these possibilities needs to occur with the patient and caregivers before implant placement. In general, it has not proved to be a significant problem in practice.

The postoperatively adjustable implants come in sizes, shapes, and volumes particularly suited to this situation. Depending on how much native breast exists, these expanders can be placed subglandularly or submuscularly.

After the patient reaches maturity, the expander can be replaced with a permanent implant, and balancing procedures to match breast shape can be performed on the opposite breast for "out of a bra" symmetry. In the patient with Poland's syndrome with significant infraclavicular soft tissue deficiency, a latissimus dorsi flap can be transferred or a custom permanent implant can be manufactured at the time of definitive reconstruction.

Extremities

Classically, the extremities have been viewed as sites where TE is of limited value and is associated with a higher risk of complications. Complication rates in the limbs have been shown to be significantly higher than non-limb sites (47% versus 23%) by Casanova et al.²² They also found an overall 19.4% complication rate in their 10-year retrospective review of more than 200 cases, including a 15.5% major complication rate and a 4.9% failure rate. Despite these prevailing opinions and ominous reports, expansion in the limbs is feasible.^{21,23} The surgeon must carefully assess the lesion or defect to be treated and understand the limitations inherent in the basic geometry of the extremities (and understand that flap movement is easier around the circumference of the limb than axially). Careful planning, choice of expander size, placement through remote incisions (in selected cases), and a possibly slower expansion schedule will lead to a lower risk of infection, extrusion, and flap failure. Unstable infected wounds are relative contraindications to TE in an extremity. Expanded pedicled flaps and expanded free flaps, such as the TRAM, deep inferior epigastric perforator (DIEP) and scapular flaps, are also powerful options for reconstructing large extremity defects.²³

For upper limb reconstruction we have devised a useful algorithm for complex defects.²³ In our experience, obtaining successful contour and color match of the upper extremity comes from approaching it in thirds (proximal arm to elbow, forearm, and the hands) and noting whether the lesion is circumferential or noncircumferential. For proximal noncircumferential defects, expanded transposition flaps from the back or shoulder serve well. If the lesion is large and circumferential, covering most of the proximal arm, and the nevus involves the adjacent back or shoulder skin, an expanded free flap is the modality of choice. Distally, for large circumferential forearm lesions, expansion of the flank creates a large pedicled flap through which the forearm can be placed during vascularization of the flap from the recipient bed (Fig. 12-14). After 3 weeks,

Fig. 12-14 Excision and reconstruction of a circumferential nevus of the arm with an expanded pedicled flap from the abdomen and flank. **A**, The patient is seen at 6 months of age, with a nevus extending from above the elbow to the wrist. **B**, The 750 cc tissue expander is shown after 12 weeks of expansion (note that the expansion is carried up onto the flap and back). **C** and **D**, The flap before division of the pedicle and after excision of all but a thin border of proximal and distal nevus. Sutures were placed to narrow the pedicle and ensure that the expanded skin gained will both fully wrap the arm and allow primary closure of the donor site. **E** and **F**, The flap was divided after 3 weeks of attachment.

Continued

Fig. 12-14, cont'd **G** and **H**, Immediately after inset of the flap. **I** and **J**, Result after excision of the remaining nevus, which was carried out 8 months after the initial flap inset. **K** and **L**, Appearance of the flap and donor site when the patient was 4 years of age, 2½ years after flap reconstruction.

the pedicle is divided. Early placement of “crimping sutures” through the pedicle helps to ensure the correct flap size at division and inset and adequate tissue for closing the donor site. Given the broad area of attachment for these flaps, complex immobilization is not required if the flap has been carefully planned so that the extremity is in a comfortable position of rest during attachment.

As previously reported, expanded full-thickness skin grafts from the abdomen or groin remain the treatment of choice for covering extensive nevi on the hand.¹⁹ Regional expansion can be used for select smaller lesions and scars of the arm and dorsum of the hand when a donor area large enough for placing the expander is available.

Expansion, although useful for treating intermediate-sized lesions of the lower extremity, is even more limited in its applications there than in the upper extremity. However, with experience, a surgeon can use expansion safely with limited risk of infection or extrusion. Expansion is easier above the knee than below it. Because of the geometry of the extremity, flaps move more easily around the circumference of the limb than axially (Fig. 12-15). Below-knee movement, even transversely, is limited. When possible, more than one expander should be used at a time. Likewise, ports should be kept at distant sites, and the expanders should be placed through smaller, nondependent incisions as much as possible (Fig. 12-16).

Fig. 12-15 TE in the thigh is limited by the geometry of the extremity and restriction of flap movement. This case of a large nevus demonstrates the need to use more than one expander when possible and the increased movement of the expanded flap that can be gained with a transposition flap versus an advancement flap. **A**, The nevus is shown before surgery in this 8-year-old child. **B** and **C**, The 750 cc and 250 cc expanders are shown after 12 weeks of expansion.

Continued

Fig. 12-15, cont'd **D** and **E**, The nevus was partially excised, leaving only a small rim of nevus in the area of the drains lateral to the knee. Transposition of the flap allowed optimal placement of the scars and avoided distortion of the thigh contour. **F**, The result is seen 1 year after excision of the final portion of the nevus, which was carried out 6 months after the initial excision.

Fig. 12-16 Soft tissue reconstruction of the lower extremity after necrotizing fasciitis. **A** and **B**, The patient presented at age 2 with a necrotizing infection that was treated with serial debridement and a meshed split-thickness skin graft. **C**, Nearly a year later, a 250 cc expander was placed in the proximal adjacent skin of the lower leg, and a 70 cc expander was placed distally near the ankle. **D**, After 11 weeks of expansion, part of the skin graft was excised, and the limb was reconstructed with expanded flaps. **E-G**, Four months after first-stage reconstruction.

Continued

Fig. 12-16, cont'd H and I, A second round of expansion was done 11 months later. This time a 500 cc expander was placed below the proximal flap, and a 70 cc expander was placed beneath the ankle flap. J and K, A short time after the second round of expansion and reconstruction after 11 weeks of expansion. L and M, Six months after the second set of surgeries, another 500 cc expander was placed into the leg. N-Q, The patient is seen at 6 years of age, 1 year after final expansion.

Treatment of large extremity defects may be better accomplished by using expansion as an adjunct to reduce the overall size of the defect, which can then be covered by free tissue transfer (the skin adjacent to the donor site is frequently expanded to allow harvest of larger flaps with primary closure of the donor site). In select cases, TE of pedicled flaps from the buttock and thigh may be used to cover the extremity below the knee after resection of a giant nevus, although this type of flap needs to be carried out in children under 1 year of age. Children older than this typically lack the flexibility to bring the lower leg against the thigh and buttock for the necessary 3 weeks of flap attachment (Fig. 12-17).

Fig. 12-17 An innovative way of using an expanded pedicled flap to cover a circumferential nevus from knee to ankle, an area where TE is of limited use, and the long-term result of grafting is often poor. **A and B,** This 1-month-old infant had a nevus with marked variegation of color, texture, and surface characteristics. The flexibility of the leg and position in relation to the planned posterior thigh donor site is demonstrated. **C,** The 350 cc expander, which was placed through an incision in the buttock region when the patient was 2 months of age, is shown near completion of expansion.

Continued

Fig. 12-17, cont'd **D** and **E**, After an intermediate delay of the flap to augment the medially based axial vascular supply, the nevus is excised and the flap wrapped around the leg, slipping the foot through the bipedicle flap that was created between the expander placement incision and the incision at the superior border of the flap. This bipedicle flap was used as the only immobilization of the flap, in addition to its large area of expanded flap attachment. **F**, Three weeks after nevus resection and flap attachment, before flap division and inset. **G**, The immediate postoperative result showing flap inset and use of the bipedicle flap, now converted to a caudally based unipedicle flap to augment tissue available for donor-site closure of the thigh.

Fig. 12-17, cont'd H and I, The result is shown 1 year after excision and expanded flap reconstruction. J-L, The patient is seen at 7 years of age, 4 months after further excision of the nevus along the scar margins.

MANAGEMENT OF COMPLICATIONS

Beyond the site-specific complications of TE mentioned previously, general complications of expansion are divided into major and minor categories. Major complications may involve infection, implant exposure, extrusion, and flap ischemia.^{15,24} Traditionally it has been taught that early postoperative infections should be managed with expander removal and antibiotics; however, as noted previously, careful attention to subtle signs of infection and maintaining a low threshold for placing the child on antibiotics again often will often prevent loss of an expander. We have also found that if a child is developing fevers and there appears to be fluid around the expander, this can be safely drained from the remote port site. This often relieves the fever, and with the use of antibiotics, can salvage the expander. The surgeon should also recognize that the augmented

Fig. 12-18 Placement of a semipermeable transparent film over exposed expanders helps protect the flap and secure the open site, preventing extrusion. Often this dressing will stabilize the wound enough that when multiple expanders are in place, the patient can complete the expansion regimen for the other expanders while maintaining the expansion already gained in the exposed expander. Reconstruction can then be carried out without loss of tissue gain.

vascular supply of an expanded flap allows safe movement of the flap to its full extent when removing an infected or exposed expander, because the primary source of the problem (the foreign body) is being removed. Careful wound irrigation with an antibiotic solution and wound drainage provide additional margins of safety.

Extrusions can be dealt with similarly. If a small area of the incision breaks down adjacent to the expander, yet the surrounding wound is stable, the expander may be salvaged and some additional expansion gained (reducing the amount injected at each expansion and varying the injection frequency). We have found that an expander is more likely to be salvageable if it lies in a dependent position in relation to the open wound. Such extrusions are also managed conservatively with local wound care and oral antibiotics. In our practice the use of semipermeable transparent dressings (Opsite, Tegaderm) to cover an exposed expander helps to support the surrounding skin and can often aid in salvage when applied in a timely manner (Fig. 12-18). Under such conditions some wounds will remain stable, with only a small area of the expander exposed, allowing completion of the intended expansion.

There are a number of minor complications associated with expansion. Pain during expansion is typically transient; however, pain noted during a fill that persists can be a sign of overexpansion. Assessment of the flap with capillary refill and firmness as a guide will alert the surgeon to this problem. Removal of some fluid will protect the flap and usually treat the pain. New-onset pain that is not temporally related to the weekly fill can often be an early sign of infection, and this should be addressed as soon as possible. Other complications include seroma, dog-ears at the donor site, partial separation at the junction points of multiple incisions, minor distal flap ischemia, and the widening of scars. Collectively, these minor events occurred at a rate as high as 17% in one study.²⁴

CONCLUSION

Tissue expansion is a powerful reconstructive tool for the treatment of a broad spectrum of pediatric congenital and acquired deformities. The augmented vascular supply gained during the expansion process allows considerable flexibility in flap design, often limited only by a surgeon's ingenuity. Successful TE in children and adults begins long before placement of the tissue expander. Careful case selection and planning are critical, as is a clear understanding of the potential limitations and complications associated with expander use.

Parents and children (when old enough) must understand why expansion is being used, the time commitments necessary for completion of the expansion, and the limitations placed on activity during the process. Preoperative teaching by an experienced nurse allows parental involvement in the expansion process, provides the groundwork for them to vigilantly observe skin changes, and acts as an avenue for rapid communication of any concerns. Combining all of these considerations, TE is extremely well tolerated by children of all ages, and even in the face of occasional complicating factors, it provides a successful approach for treating many reconstructive problems.

KEY POINTS

- Successful expansion, regardless of indication, relies on careful case selection.
- TE in children is not associated with a higher risk of complications than in adults, and it is extremely well tolerated.
- Safe expansion in the pediatric population begins with careful assessment of each patient. This includes determining whether TE is the optimal technique for the reconstruction planned, whether the patient and/or the parents will be able to manage the routines necessary, whether there is a clear understanding of the potential complications, and whether the time constraints inherent in the process can be accommodated in the specific situation.
- When appropriate, TE at home is possible, safe, and advantageous to the patient and family. It requires close interaction and preoperative and postoperative instruction by the nursing staff and physician.
- The surgeon must understand the potential problems and avoid them.
- The choice of expander, incision for placement, and expansion routine may vary according to the site of expansion and the underlying defect being treated.

Continued

KEY POINTS (continued)

- TE can safely begin in the scalp at 6 months of age, and some cranial molding is to be expected, but there has been no demonstrated risk of long-term cranial deformation.
- Expanded transposition flaps in the head and neck, trunk, and, to a lesser extent, the extremities allow much greater use of expanded skin flaps than traditional expanded advancement flaps.
- The average length of time between placing an expander and reconstruction with flap movement is 10 to 11 weeks, with 3 to 4 months between each set of expanders for serial expansion.
- The combined use of expanded flaps and expanded full-thickness skin grafts provides optimal aesthetic and functional reconstruction in the face and periorbital area, with the former used for reconstructing the forehead and cheek and the latter used for the periorbital area and eyelids.
- Our experience has demonstrated that a higher rate of complications in nonnevus cases may require variation in technique.
- Expansion can be used safely in the extremities but is limited, because expanded flaps move better for coverage circumferentially than axially.
- Expanded pedicled flaps from the abdomen and flank can be used effectively to cover large circumferential defects of the upper extremities in infants and children.
- Perhaps the most important guiding principle for avoiding complications (especially flap compromise) is to reexpand flaps rather than try to overextend them.

Radiologic Management of Vascular Anomalies

Philip R. John

There are two broad categories of vascular anomalies: vascular tumors and vascular malformations. This original division, which was proposed by Mulliken and Glowacki,¹ was based on the biologic and clinical behavior of these anomalies, including their physical characteristics, natural history, and cellular features. Since then, additional disease entities of varying complexity have been identified, some of which are not easily defined by the original classification. An updated classification was presented in 2014 at the Twentieth Congress of the International Society for the Study of Vascular Anomalies (ISSVA) and is now accepted as the most up-to-date classification of vascular anomalies.² This updated ISSVA classification has modifications with expansion of the subcategories² (Boxes 13-1 and 13-2). This more comprehensive classification provides an excellent framework for the medical community to use when managing patients with vascular anomalies.

A few vascular anomalies remain unclassified because of uncertainty whether they are tumors or malformations, or because their clinicopathologic features are not fully understood. Included in this group are Verrucous hemangiomas and angiokeratomas, kaposiform lymphangiomatosis, and PTEN hamartoma of soft tissue.²

Box 13-1 ISSVA Classification of Vascular Anomalies: 2014**Vascular Tumors**

- Benign
 - Infantile hemangioma
 - Congenital hemangioma
 - Tufted angioma
 - Pyogenic granuloma
 - Others
- Locally aggressive/borderline vascular tumors
 - Kaposiform hemangioendothelioma (KHE)
 - Dabska tumor
 - Kaposi sarcoma
 - Others
- Malignant vascular tumors
 - Angiosarcoma
 - Epithelioid hemangioendothelioma
 - Others

Vascular Malformations

- Simple
 - Capillary malformation (CM)
 - Venous malformation (VM)
 - Lymphatic malformation (LM)
 - Arteriovenous malformation (AVM)
 - Arteriovenous fistula (AVF)
- Combined
 - CM + VM/LM/AVM
 - CM + LM + VM/AVM
 - CM + VM + AVM
 - CM + LM + VM + AVM
- Of major named vessels
 - Affecting origin, course, number, length, diameter, or valves of larger veins/arteries/lymphatics. Includes persistence of embryonic vessels.
- Associated with other anomalies
 - Klippel-Trenaunay syndrome (KTS) (CM + VM ± LM + limb overgrowth)
 - Parkes Weber syndrome (CM + AVF + limb overgrowth)
 - Servelle-Martorell syndrome (limb VM + bone undergrowth)
 - Sturge-Weber syndrome (facial + leptomeningeal CM + ocular anomalies ± bone and/or soft tissue overgrowth)
 - Maffucci syndrome (VM ± spindle cell hemangioma + enchondroma)
 - CLOVES syndrome (congenital, lipomatous, overgrowth, vascular malformations, epidermal nevi, spinal/skeletal anomalies and/or scoliosis [LM + VM + CM ± AVM + lipomatous overgrowth])
 - Proteus syndrome (CM, VM ± LM + asymmetric somatic overgrowth)
 - Phosphatase and tensin homolog (PTEN) hamartoma-tumor syndrome, previously called Cowden syndrome or Bannayan-Riley-Ruvalcaba syndrome (AVM + VM + macrocephaly, lipomatous overgrowth)

Box 13-2 ISSVA Classification of Simple Vascular Malformations: 2014**Capillary Malformations**

- Cutaneous and/or mucosal CM (port-wine stain)
- CM with bone/soft tissue overgrowth
- CM-AVM
- Others

Lymphatic Malformations

- Common (cystic) LM—macrocytic, microcytic, mixed cystic LM
- Generalized lymphatic anomaly (GLA)
- LM in Gorham-Stout disease
- Channel-type LM
- Primary lymphedema
- Others

Venous Malformations

- Common VMs
- Familial VM cutaneomucosal (VMCM)
- Blue rubber bleb nevus syndrome
- Glomuvenous malformation (GVM)
- Cerebral cavernous malformation (CCM, different types)
- Others

Arteriovenous Malformations and Arteriovenous Fistulas

- Sporadic
- In hereditary hemorrhagic telangiectasia (HHT)
- In CM-AVM

CM, Capillary malformation; CM-AVM, capillary malformation-arteriovenous malformation; ISSVA, International Society for the Study of Vascular Anomalies; LM, lymphatic malformation; VM, venous malformation

Establishing an accurate diagnosis and using the correct terminology are vital for appropriate patient assessment and management and avoiding inappropriate treatments. Unfortunately, confusion remains throughout the medical community regarding vascular anomalies and incorrect descriptions of these diseases, and misdiagnoses are not uncommon. Most postnatal diagnoses can be made from medical history and physical examination, supplemented with diagnostic imaging (and occasionally other investigations) when diagnoses are unclear or lesions are deeply located.

Infantile hemangiomas are the most common type of vascular tumor, initially presenting a few weeks after birth. Fetal hypoxic stress is considered a likely trigger for the development of these tumors; however, placental emboli have previously been implicated, because they have pathologic features in common. *Congenital hemangiomas*, which arise in utero and are maximal in size at birth in a full-term infant, are morphologically and biologically different than infantile hemangiomas, and their cause is not well understood. *Vascular malformations* are different than infantile hemangiomas, because they are present at birth (although not always evident), show commensurate growth with the patient, and persist throughout life. Vascular malformations are caused by errors

in vascular development during embryogenesis. The entire spectrum of vascular channels (capillary, venous, lymphatic, and arterial) can be affected, resulting in *low-flow malformations* (capillary, venous, or lymphatic malformations) or *high-flow malformations* (arteriovenous malformations [AVMs] and arteriovenous fistulas [AVFs]). In high-flow malformations, shunting of blood occurs between arteries and veins without an intervening capillary bed. Causal genetic anomalies are now recognized in several vascular malformations. For example, somatic mutations of the *Tie2* gene are seen in more than 50% of the sporadic “common type” of venous malformations. Although most vascular tumors are not associated with malformations, the so-called “segmental” type of infantile hemangioma may be associated with developmental vascular and other anomalies, such as in PHACES syndrome.³

Many patients will benefit from a multidisciplinary team approach. The interventional radiologist plays an important role on the multidisciplinary team by providing treatment options for some of these patients, particularly those with selected vascular malformations. Most treatments are performed electively; however, some may be required in emergent situations, such as in infants who have life-threatening cardiac failure resulting from large intrahepatic vascular shunts from hepatic hemangiomas and AVMs.

Interventional radiologic techniques provide “keyhole” percutaneous or endovascular approaches with imaging guidance. Procedures are carried out using a general anesthetic with full sterile technique in an angiography suite. The three main techniques for treating low-flow vascular malformations are sclerotherapy, venous embolization, and endovenous laser ablation. Sclerotherapy involves the injection of a sclerosant liquid/foam using a needle directly into the vascular channels within the malformation, whereas venous embolization involves the injection of sclerosants or occlusive devices through a catheter. Most patients with low-flow malformations treated by sclerotherapy are discharged from the hospital within 4 to 6 hours after the procedure. High-flow malformations can be treated by arterial or venous catheter embolization or by direct injection into the nidus of an AVM. High-flow malformation treatments usually require a 24-hour hospital stay before discharge. The interventional radiologist works as part of a multidisciplinary team. Sometimes radiologic treatments must be combined with surgical resection and debulking procedures, as well as combined with various medical therapies to achieve optimal results.

As a physician, the interventional radiologist sees the patient before and after the procedure and provides early and late follow-up for all patients. For elective cases, the radiologist should assess the patient and review all investigations, including recent imaging before the procedure. Arrangements are made for any necessary periprocedural, intraoperative, and postoperative care. For example, if significant swelling is likely after treatment in lesions located in the oral cavity (including the tongue) or airway, then planned admission to the intensive care unit may be needed for airway support and management. If multiple treatments are required over a long period for large anomalies affecting the oral cavity and airway (particularly in infancy), gastrostomy and tracheostomy may be required for feeding and airway support, respectively. Postoperative requirements vary and can be dependent on patient age, patient well-being (including psychosocial), and disease type and location. For example, large pelvic or urogenital malformations may require a Foley catheter for several days until postoperative swelling resolves. Steroids, antibiotics, and NSAIDs may be required as single intravenous doses for selected sclerotherapy and embolization procedures. Dexamethasone (0.1 mg/kg, maximum 8 mg) is given if the lesion is in a confined space, such as the orbit or airway and in locations where there is a risk of compartment syndrome. Cefazolin (30 mg/kg, maximum 1 g) should be given when treating oral, orbital, or perineal/perianal lesions. Ketorolac (0.5 mg/kg, maximum 15 mg in those less than 16 years of age, repeated every 6 hours) is an effective postoperative analgesic.

ROLE OF DIAGNOSTIC IMAGING

Not all patients with vascular anomalies require imaging to confirm the diagnosis. Most (more than 80%) can be diagnosed based on clinical history and physical examination; for example, most babies with infantile hemangiomas do not need imaging.⁴

Imaging is performed to aid in diagnosis and when full evaluation of the anomaly is required to assess the full extent of the disease. Ultrasonography and MRI are the most useful modalities because of their high tissue specificity.⁵ For most patients, magnetic resonance angiography (MRA) sequences are not required for diagnosis. In patients with high-flow lesions, MRA is useful for mapping the affected vascular anatomy and seeing if the lesion is embedded in fat. Ultrasonography has limitations when lesions are extensive or deeply located.

There is much “pattern recognition” on diagnostic imaging, as there is with the clinical assessment of patients, when dealing with vascular anomalies. The diagnostic radiologist must be familiar with these conditions. The radiologist should always request accurate and adequate information when the patient is referred for imaging. Knowing the patient’s age when the abnormality was first noticed and any change in lesion size as the patient has grown is vital information to help distinguish tumors from malformations. To fully evaluate the anomaly, imaging must include the entire extent of the disease. If imaging is performed to assess a hemangioma, it is useful to know the type of hemangioma (infantile/congenital), and if it is an infantile hemangioma, the phase of the life cycle of the hemangioma at the time of imaging.

Vascular tumors on MRI and ultrasonography have a parenchymal tumor showing hypervascularity and sometimes vascular shunting (Figs. 13-1 through 13-3). Depending on the tumor type and its natural history, the vascularity and shunts may vary; the degree of contrast enhancement on MRI varies and fibrofatty replacement of some tumors can occur. Tumors that are proliferative show significant hypervascularity on ultrasonography and significant contrast enhancement on MRI.

Fig. 13-1 Typical ultrasonography of infantile hemangioma. **A**, Proliferative phase of parotid infantile hemangioma. The solid echogenic tumor parenchyma is hypervascular with a high vessel density. The solid parenchymal component of the infantile hemangioma distinguishes it from an AVM. **B**, Early involutory phase of two cutaneous infantile hemangiomas.

Continued

Fig. 13-1, cont'd **C**, Increased reflectivity to the base of the lesion in the subcutaneous tissues resulting from fibrofatty changes. **D**, Reduced hypervascularity and vessel density during involution on color Doppler.

Fig. 13-2 Typical MRI features of the proliferative phase of infantile hemangioma. **A**, Parotid hemangioma shows that tumor parenchyma is isointense on T1-weighted sequence. **B**, Hyperintense on T2-weighted sequence. **C**, Avid uniform contrast enhancement.

Fig. 13-3 Orbital proliferative infantile hemangioma. **A**, MRI shows typical flow voids in a proliferative tumor in a baby. Flow voids are seen as small channels of signal loss. **B**, Orbital hemangioma.

Vascular malformations on MRI and ultrasonography show no parenchymal tumor. Venous malformations have dysplastic venous spaces, thrombi, and phleboliths (Figs. 13-4 and 13-5). Lymphatic malformations have variable-sized cysts; some contain hemorrhagic fluid or thrombi adjacent to the cyst walls (Figs. 13-6 and 13-7). The microcystic type of lymphatic malformations have cysts so small that the cyst cavities cannot be identified on imaging and appear as areas of “solid” tissue, which is echogenic on ultrasonography. Venous malformations and lymphatic malformations can have fluid-fluid levels. Contrast enhancement during MRI is useful to distinguish venous malformations from lymphatic malformations. AVMs show lesional hypervascularity and vascular shunting on ultrasonography and MRI. Perilesional soft tissue edema can be seen on MRI.

Fig. 13-4 Typical ultrasonography features of soft tissue venous malformation. **A**, Anechoic venous channels with the lesion, which has a spongeliike structure. **B**, Typical phlebolith (calcification in thrombus) present in venous malformation channel.

Fig. 13-5 Typical MRI features of venous malformation. **A**, Left facial intermittent swelling with normal overlying skin. **B**, The intramuscular venous malformation is isointense on T1 sequence. Intralesional hyperintense focal area before contrast is caused by intralesional thrombus. **C**, Hyperintense on T2 sequence. **D**, Nonuniform lesion enhancement with IV contrast is seen.

Fig. 13-6 Typical ultrasonographic features of cystic lymphatic malformation. **A**, Macrocystic lymphatic malformation. **B**, Microcystic lymphatic malformation. Cystic cavities of varying size are easily seen on macrocystic disease and are suitable for injection sclerotherapy. Pure microcystic lymphatic malformation appears as solid echogenic tissue with no ultrasonography visible cysts and is unsuitable for injection sclerotherapy.

Fig. 13-7 Typical MRI features of cystic lymphatic malformation. **A-C**, Macrocystic chest wall lymphatic malformation. **D-F**, Microcystic lymphatic malformation of the forearm in the same patient shown in Fig. 13-6, *B* and Fig. 13-20, *E*. **B**, Both macrocystic and microcystic lymphatic malformations have similar T1 (**A** and **D**) and T2 (**B** and **E**) signal intensity (isointense on T1, hyperintense on T2). IV contrast can differentiate macrocystic from microcystic lymphatic malformation. **C**, Cyst rim enhancement occurs in macrocystic lymphatic malformation. **F**, Microcystic lymphatic malformation sometimes shows a faint diffuse enhancement throughout the lesion.

Localized increased fatty areas can be seen around some soft tissue venous malformations and AVMs. Enlargement of inflow arteries and outflow veins with AV shunting can be seen in both vascular tumors and high-flow vascular malformations.

Bedside ultrasonography is extremely useful for assessing vascular anomalies in a clinic setting and provides a rapid diagnosis when there is a clinical dilemma. For example, if a young infant has a slightly blue-colored soft tissue swelling, bedside ultrasonography can yield an immediate answer if it is caused by a subcutaneous infantile hemangioma, a venous malformation, or by bleeding into a small macrocystic lymphatic malformation. This is operator dependent and relies on the operator's familiarity with the ultrasonographic appearances of these disorders. This bedside ultrasound assessment is no substitute for more formal imaging in a radiology department. The interventional radiologist is well suited to carry out such bedside ultrasonography when needed in the clinic setting.

Plain radiographs and CT scans are not required for most diagnoses, because they have low-contrast resolution and tissue specificity. However, they may be required to assess abnormalities of skeletal growth associated with vascular malformations, to assess extremity overgrowth such as in Klippel-Trenaunay syndrome (KTS) and to evaluate vascular malformations involving the skeleton (Fig. 13-8). Conventional venography and catheter angiography are not required in most patients. Venography is occasionally performed in venous malformations with significant

Fig. 13-8 A-C, Lateral marginal embryonic vein in KTS. **A** and **B**, Venogram of the vein performed by direct injection into the vein below the knee showing a single large channel, communicating with a superficial venous aneurysm below the knee. **B**, The embryonic vein drains through posterior channels in the upper thigh to the femoral vein and transgluteal channels to the iliac vein. This embryonic vein is frequently made up of multiple intercommunicating channels.

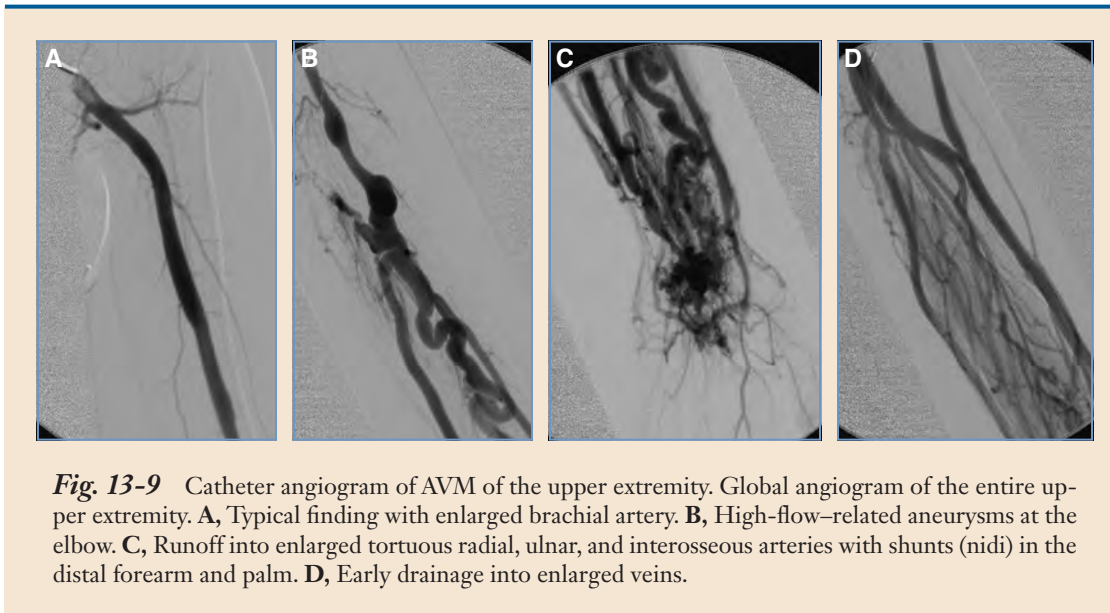

Fig. 13-9 Catheter angiogram of AVM of the upper extremity. Global angiogram of the entire upper extremity. **A**, Typical finding with enlarged brachial artery. **B**, High-flow-related aneurysms at the elbow. **C**, Runoff into enlarged tortuous radial, ulnar, and interosseous arteries with shunts (nidi) in the distal forearm and palm. **D**, Early drainage into enlarged veins.

phlebectasia to assess potential closure methods and in some patients to delineate communications between the venous malformation and normal functioning veins. This can be performed at the time of sclerotherapy. In KTS, venography to assess anomalous veins and the deep venous system before endovascular therapy is required because magnetic resonance venography (MRV) is often inadequate. Catheter arteriography is performed during embolization in selected high-flow vascular anomalies (Fig. 13-9). Nuclear medicine has no role in imaging these disorders.

VASCULAR TUMORS

Infantile Hemangioma

Infantile hemangioma is the most common tumor of infancy, appearing a few weeks after birth and located in the skin, often in the head and neck area.⁶ Infantile hemangiomas have an incidence of 1.0% to 2.6% in white neonates, which increases significantly in preterm babies. Twenty percent of babies have multiple lesions; when internal, the lesions can be present in the liver, gastrointestinal tract, and brain. Infantile hemangiomas have a characteristic three-phase life cycle (see Fig. 13-9). The first or *proliferative phase* occurs within the first 9 to 12 months of postnatal life and is characterized by rapid tumor growth and tumor angiogenesis. During this phase tumors are hypervascular and vascular shunting can be seen. The second or slow *involuting phase* occurs between 1 and 5 to 7 years of age, with reduced angiogenesis and reduction in overall size. Reduced vascular flow and some fibrofatty replacement occurs. The third or *involved phase* occurs after 5 to 7 years, with resultant fibrofatty residue, small capillaries, and draining veins (Fig. 13-10). After involution, lesions do not recur, and approximately half of all patients will have near-normal looking skin at the site of the lesion.

When the superficial dermis is involved, infantile hemangiomas present as red lesions and become raised. Ulceration and bleeding can be seen in large superficial tumors with rapid growth. Tumors in the lower dermis and subcutaneous tissue appear bluish or have no alteration in color to the overlying skin. During involution, the color of the tumor fades.

Infantile hemangiomas can be mistaken for capillary malformations. Deep (for example, subcutaneous) infantile hemangiomas can be mistaken for venous malformations or lymphatic malformations because of the bluish discoloration through the skin. Infantile hemangiomas showing

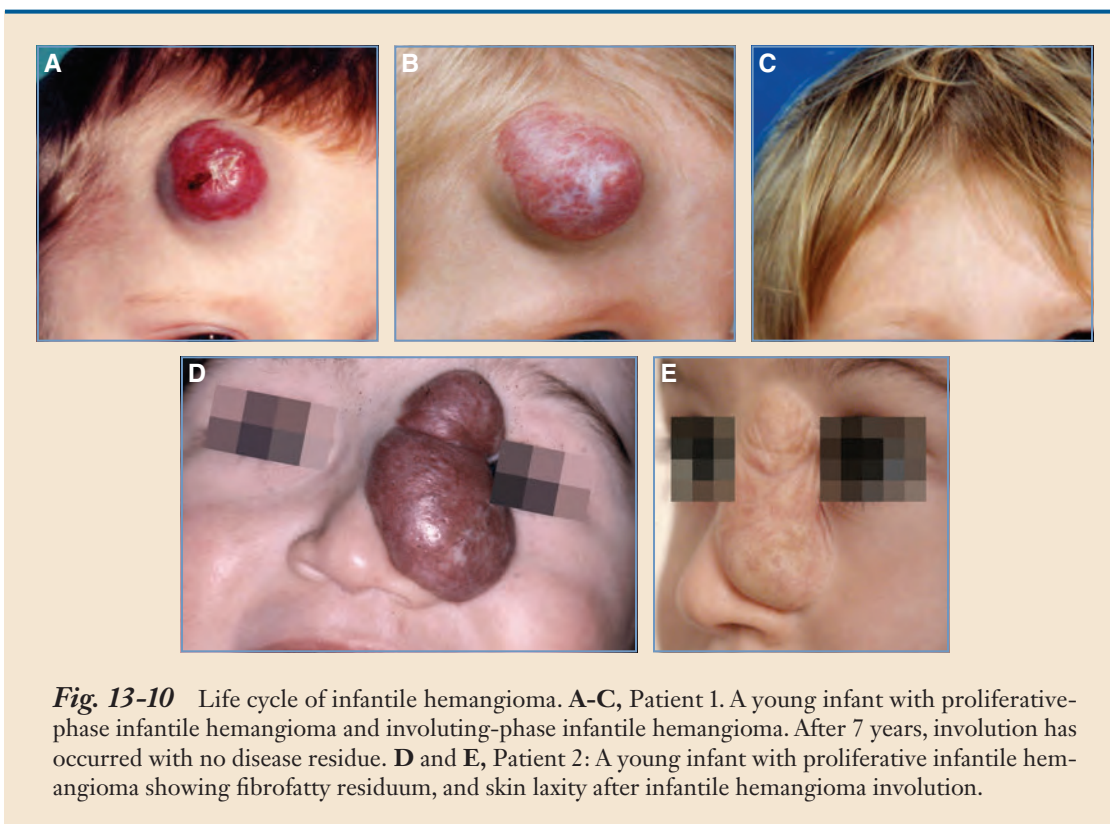

Fig. 13-10 Life cycle of infantile hemangioma. **A-C**, Patient 1. A young infant with proliferative-phase infantile hemangioma and involuting-phase infantile hemangioma. After 7 years, involution has occurred with no disease residue. **D** and **E**, Patient 2: A young infant with proliferative infantile hemangioma showing fibrofatty residuum, and skin laxity after infantile hemangioma involution.

high flow can be mistaken for AVMs, but the age at onset, growth pattern, and presence of tumor parenchyma in an infantile hemangioma distinguishes it from an AVM.

The location of the infantile hemangioma may be associated with specific problems during the proliferative phase when the tumor is rapidly increasing in size. Airway obstruction, visual impairment, gastrointestinal bleeding, high-output congestive heart failure from vascular shunting within large or multiple hemangiomas (particularly in the liver), and tissue necrosis can potentially occur.

Imaging of Infantile Hemangioma

On ultrasonography, infantile hemangiomas are well-defined masses during the proliferative phase with a nonspecific echogenicity, which is either hyperreflective or hyporefective (see Fig. 13-1). High vessel density, high Doppler frequency shifts, and low resistive indexes are characteristic of proliferative infantile hemangiomas⁷ (see Fig. 13-1). During involution, the lesion becomes smaller with decreased vessel density. However, vessels usually maintain high Doppler frequency shifts. Fibrofatty changes, especially at the base of infantile hemangiomas, occur with involution (see Figs. 13-2 and 13-3 for the typical MRI appearance of proliferative infantile hemangioma).

Congenital Hemangioma

Congenital hemangiomas are rare and are distinct from infantile hemangiomas.^{8,9} They arise antenatally and are fully developed at birth. They do not usually exhibit postnatal growth unless infants are preterm, when they will continue to grow for some time. There are three recognized types of congenital hemangiomas: (1) *rapidly involuting congenital hemangioma* (RICH), (2) *non-involuting congenital hemangioma* (NICH, Figs. 13-11 through 13-14), and (3) *partially involuting*

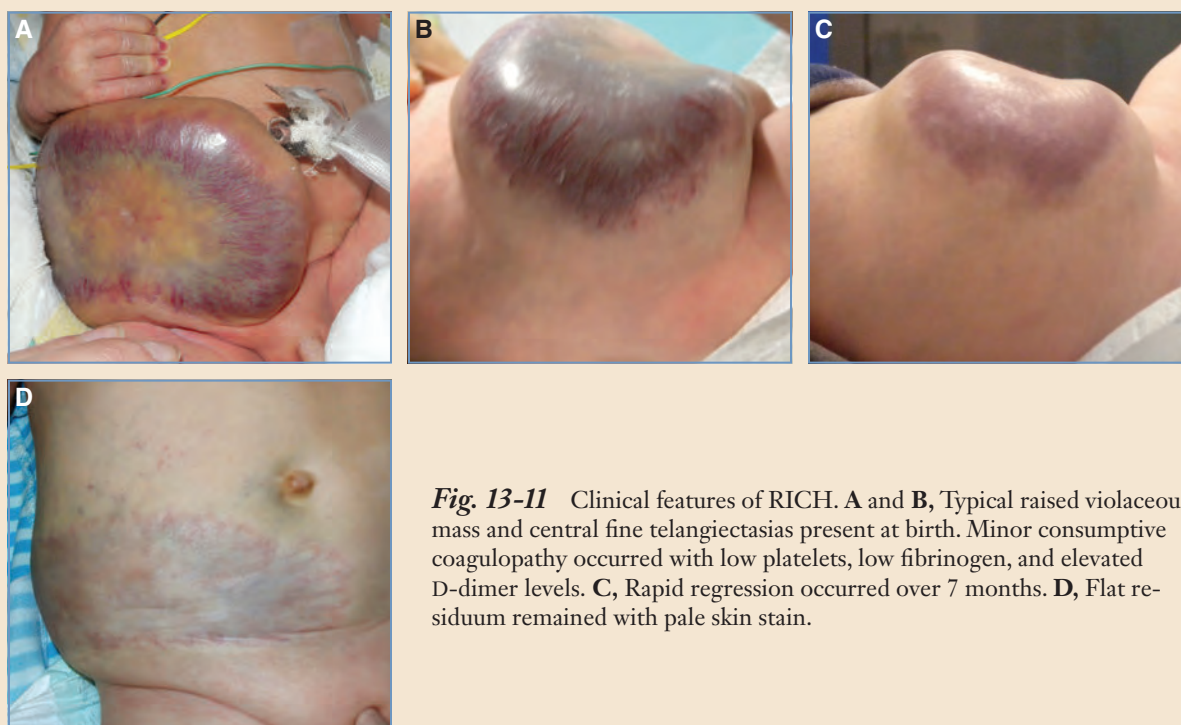

Fig. 13-11 Clinical features of RICH. **A** and **B**, Typical raised violaceous mass and central fine telangiectasias present at birth. Minor consumptive coagulopathy occurred with low platelets, low fibrinogen, and elevated D-dimer levels. **C**, Rapid regression occurred over 7 months. **D**, Flat residuum remained with pale skin stain.

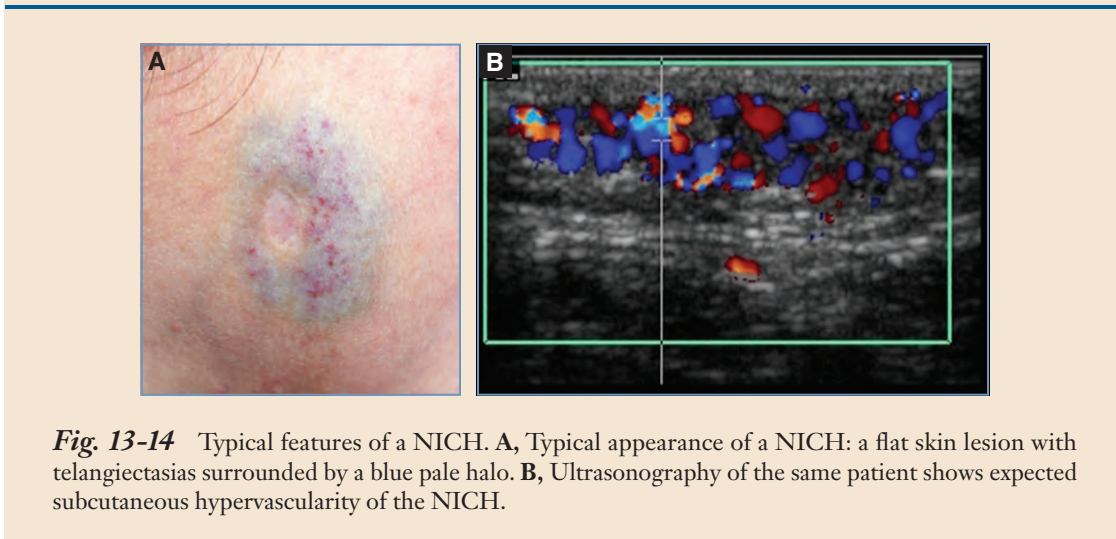

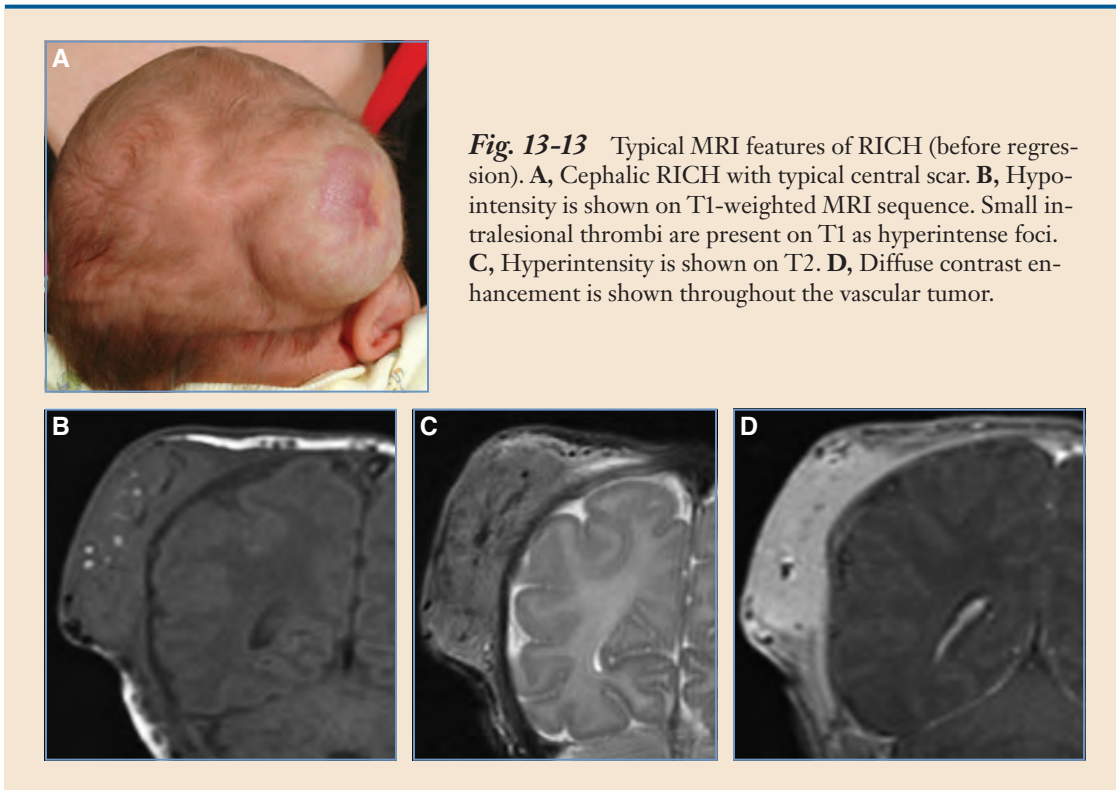

Fig. 13-12 Typical ultrasonography features of RICH (before regression). **A**, Typical vascular soft tissue tumor containing anechoic vascular spaces. **B** and **C**, Marked hypervascularity with prominent arterial inflow and venous outflow on color Doppler imaging.

congenital hemangioma (PICH). Clinically, these three types of congenital hemangiomas are quite different. RICHs are often impressive protuberant masses, with a predilection for the craniofacial region and extremities, whereas NICHs tend to be flat to slightly raised, rounded skin lesions, with telangiectasias and a pale surrounding halo. RICHs show spontaneous accelerated regression between 6 and 14 months of postnatal life, whereas NICHs persist throughout life. Before regression, two complications can be seen in the RICH, although both are uncommon: cardiac overload and transient thrombocytopenia. Significant arteriovenous shunting can occur within the tumor, leading to cardiac failure. The thrombocytopenia typically occurs in the first

week in large RICH tumors, and platelet count rapidly returns to normal levels as the RICH regresses. A PICH has overlapping features of a RICH and a NICH; however, even though it can resemble a RICH initially, it never fully regresses. Congenital hemangiomas can potentially be confused with vascular malformations. However, the clinical features and the presence of tumor parenchyma provide clues to the antenatal and postnatal diagnosis of congenital hemangiomas. These tumors, although called “hemangiomas,” are quite distinct from infantile hemangioma. Interestingly, hemangiomas may be seen with features in common with both tumor types (infantile hemangioma and congenital hemangioma) in the same lesion.

Imaging of Congenital Hemangioma

Distinctive imaging characteristics are observed in a congenital hemangioma.⁹ On ultrasonography, prominence of vascular channels and calcifications are seen in contrast to infantile hemangioma. On MRI, the tumor margins may be less defined compared with infantile hemangioma⁹ (see Figs. 13-12 through 13-14).

Infantile Hepatic Hemangioma

Visceral hemangiomas may be associated with multiple cutaneous infantile hemangiomas (more than five). However, they can occur without cutaneous hemangiomas. The liver is the most common organ affected by hemangiomas. The three types of *infantile hepatic hemangiomas* (IHHs) are focal, multifocal, and diffuse¹⁰ (Fig. 13-15). The classic presentation of IHH with the symptoms of heart failure, anemia, and hepatomegaly is rare, and certainly not all hepatic hemangiomas are life-threatening. Most infantile hepatic hemangiomas, even if multifocal, are asymptomatic.

Focal lesions are often large and present antenatally. They do not grow after birth, with regression usually seen in the first 12 to 14 months of postnatal life (similar to a RICH). Multifocal hepatic hemangiomas are similar in behavior to the typical cutaneous infantile hemangiomas with a three-phase life cycle. Macrovascular shunts, if present in the focal and multifocal IHHs, can lead to high-output cardiac failure and require emergent catheter embolization, which is sometimes performed as staged procedures.¹⁰⁻¹² In focal IHH, the onset of cardiac failure is usually at or soon after birth. In multifocal IHHs, the onset of cardiac failure may not occur for several months after birth. Embolization should be performed in conjunction with other intensive medical support and medical therapy (including steroids and beta-blockers, the latter being used with caution in cardiac failure) to promote tumor involution. In the diffuse type, most of the liver parenchyma is replaced by tumor, typically causing massive hepatomegaly, abdominal compartment syndrome, and respiratory compromise. The diffuse type can lead to severe hypothyroidism until there is tumor involution because the tumor produces type 3 iodothyronine deiodinase, which inactivates circulating thyroid hormones. Large thyroxine doses are required by these infants.

Fig. 13-15 IHH. The three types of IHH are shown: **A**, Focal. **B**, Multifocal. **C**, Diffuse. **A** and **B** are T2-weighted MRI sequences, whereas **C** is a postcontrast CT scan.

Fig. 13-16 KHE. **A**, Typical appearance of KHE with violaceous tumor. **B**, MRI (T2-weighted sequence) shows a hyperintense soft tissue tumor with typical subcutaneous stranding from dilated subdermal lymphatics. **C** and **D**, Selective microcatheter angiography shows typical hypervascular tumor with no shunting.

Kaposiform Hemangioendothelioma and Tufted Angioma

These sometimes aggressive and invasive vascular tumors are often present at birth. However, they can also present later. *Kaposiform hemangioendothelioma* (KHE) is usually more extensive than *tufted angioma*. The tumors are often located on the trunk, shoulder, thigh, or retroperitoneum.¹³ Tufted angioma appears as a red skin plaque and KHE as a violaceous skin lesion. MRI is excellent at evaluating these rare vascular tumors (Fig. 13-16). Tissue biopsy is not always required; however, a percutaneous image-guided needle biopsy can be helpful. Histologic findings reveal infiltrating sheets of slender endothelial cells with positive staining for lymphatic elements.

There is no role for interventional radiology in the treatment of tufted angioma or uncomplicated KHE.

Kasabach-Merritt Syndrome

Kasabach-Merritt syndrome refers to thrombocytopenia from platelet consumption associated with a coagulopathy and occurs only with two specific vascular tumors, KHE and tufted angioma. It does not occur in other vascular tumors or any vascular malformation.

Typically, the thrombocytopenia is severe, with a platelet count below $10 \times 10^9/L$. The coagulopathy occurs with reduced fibrinogen levels and elevated prothrombin and partial thromboplastin times. Bleeding is often evident. Treatment for most patients is medical, because tumors

Fig. 13-17 Catheter embolization of KHE. **A** and **B**, Typical angiographic appearance of KHE with tumor staining. During arterial catheter embolization, particles (for example, polyvinyl alcohol) are used to devascularize the tumor parenchyma. **C**, Angiographically, particles are delivered to reduce the tumor stain and preserve the main arterial trunks.

may be large and extensive.^{14,15} Supportive measures in critical care may be needed. Low-dose weekly IV vincristine and oral corticosteroids are usually given. More recently, rapamycin (sirolimus) has also been used effectively. In Kasabach-Merritt syndrome, the mortality rate is between 20% and 30%, and tumors show proliferation into early childhood with eventual incomplete regression despite being otherwise asymptomatic. Platelet transfusions are usually reserved for patients with platelet counts below $10 \times 10^9/L$ when there is a risk of spontaneous intracranial hemorrhage. Routine platelet transfusion is not recommended, because this can lead to an increase in tumor size.

Transcatheter arterial embolization with polyvinyl alcohol particles (size range 250 to 350 μ) can improve the thrombocytopenia (Fig. 13-17) and may need to be repeated. Particle embolization should be considered adjunctive therapy if the thrombocytopenia is refractory to medical treatment with pharmacologic agents.

Vascular Tumor Treatment

Most infantile hemangiomas do not require specific treatment other than observation and reassurance to the family. In particular, the interventionalist has no role in the majority of infants with vascular tumors.

Previously, approximately 10% of infantile hemangiomas were treated medically, because they were “endangering” by virtue of their location or functional risks (for example, airway compromise or heart failure). Today, more infants with cutaneous infantile hemangiomas are offered medical treatment during the proliferative phase. Oral beta-blockers (propranolol) or angiogenesis inhibitors, mainly corticosteroids (prednisone), are commonly used. Topical beta-blockers are now being used in selected lesions. Intralesional corticosteroid injection may be performed for infantile hemangiomas that cause local deformity or ulceration. Ultrasonographic guidance can help to target the injection into the solid tumor component. Systemic low-dose chemotherapy with vincristine (through a central venous line or a peripherally inserted central catheter line) may be considered additional therapy in challenging cases.

In selected patients, other options can be offered, such as surgery with excision and debulking. Surgical resection is sometimes performed for infantile hemangiomas during and after the involuting phase and also for NICHs. An Nd:YAG laser with epidermal ice cooling has been recommended as an option to treat the deeper subcutaneous component of infantile hemangiomas.

Fig. 13-18 Catheter angiography and embolization in proliferative phase infantile hemangioma. An infant with a large parotid infantile hemangioma. Typical angiographic findings. **A**, Enlarged feeding facial artery. **B**, Marked tumor parenchymal staining. **C**, Enlarged draining external jugular vein typical of proliferative infantile hemangioma. **D**, Particle embolization results in significant devascularization. NOTE: Most infants with infantile hemangioma do not require catheter angiography and embolization.

It is important to wait for complete regression of RICHs and completed involution in infantile hemangiomas before plastic surgery is considered to deal with cosmetic issues.

Catheter angiography and embolization is rarely needed for infants with vascular tumors. However, it can be extremely useful and sometimes lifesaving when endovascular closure of macroshunts or devascularization of the tumor bed is required (see Fig. 13-17; Fig. 13-18).

Catheter embolization is a useful technique in a few selected infants in the following clinical situations:

1. To reduce the tumor vascular shunting when infants are in cardiac failure
2. To devascularize the tumor if there is refractory tumor bleeding
3. To devascularize the tumor in Kasabach-Merritt syndrome when it is not responsive to conventional medical management
4. To devascularize the tumor before surgical excision, if there are concerns about intraoperative blood loss

Angiography and catheter embolization in infancy require much expertise. Arterial catheterization can be challenging in infancy, because of small access vessel sizes. In a full-term infant, the common femoral artery has a diameter of 2 mm, and the diameter of the brachial artery is approximately 1.5 mm. It is essential to use small angiographic catheters (for example, 3 Fr or 4 Fr), safe volumes of radiologic contrast, and systemic heparinization during catheterization to minimize catheterization times and to maintain patient well-being, including body temperature and fluid balance. Familiarity with vascular anatomy and variable shunts is essential. Because staged

embolization may be required, it is important to avoid routine diagnostic catheter angiography in infants unless it is combined with embolization to preserve vital arterial access. Embolic agents can be safely delivered through a microcatheter, which is advanced to the target through an outer 4 Fr guiding catheter. Embolic agents used to treat vascular tumors include N-butyl-2 cyanoacrylate (NBCA) glue (Histoacryl), polyvinyl alcohol microparticles, microcoils, and occasionally small vascular plugs. Ethanol and sodium tetradecyl sulphate (STS) should not be used as embolic agents for vascular tumors, because they can cause extensive tissue necrosis.

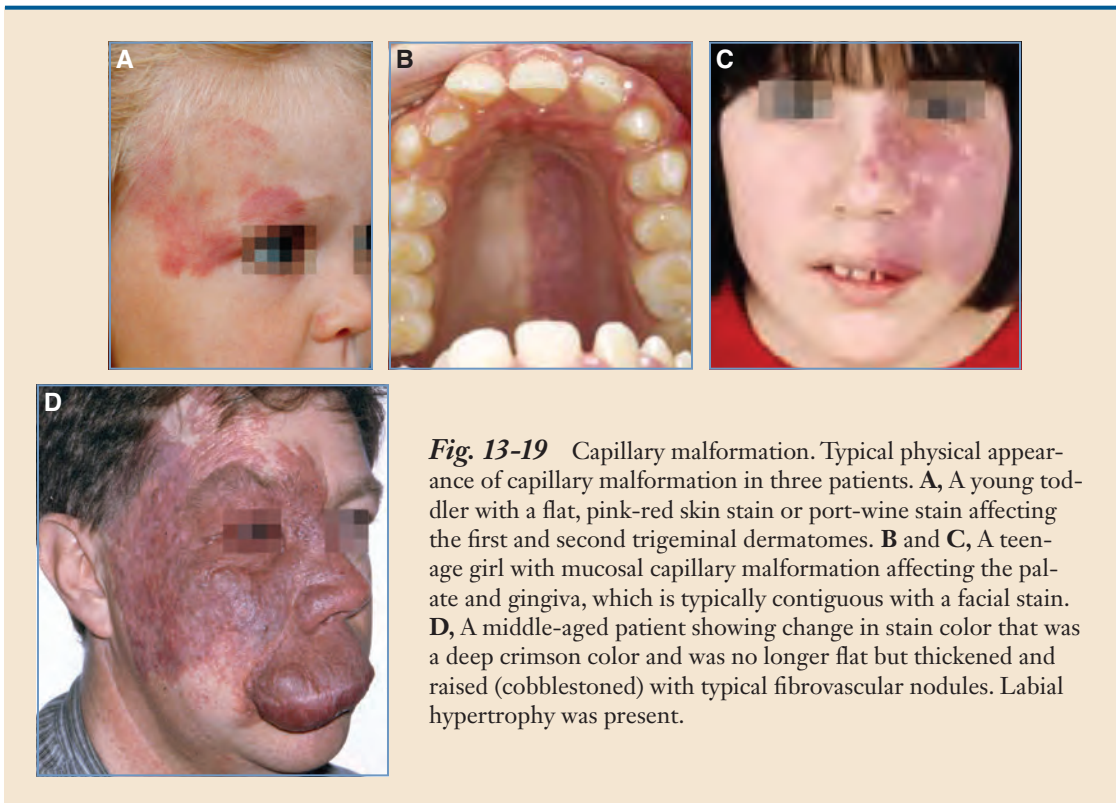

VASCULAR MALFORMATIONS

Vascular malformations are quite rare, with an estimated incidence of approximately 0.3%. They are typically sporadic (with no family history); however, they can sometimes occur as incompletely penetrant, inherited traits. The genetic basis of several malformations has been identified, and to date, genetic advances have predominantly been seen in the rare, familial forms.

Capillary Malformation

A *capillary malformation* is the most common vascular malformation and at birth is a flat, pink-red, low-flow cutaneous lesion. Capillary malformations are commonly called *port-wine stains* and frequently are located as focal skin stains in the head and neck area (Fig. 13-19). They can also be mucosal. Capillary malformations can be localized or extensive. They do not fade and are permanent (see Fig. 13-19).

Syndromic capillary malformations occur more rarely, such as in *Sturge-Weber syndrome* (SWS), in which the capillary malformation is located on the face and affects the first and sec-

ond trigeminal dermatomes (see Fig. 13-19). Sturge-Weber syndrome is associated with ipsilateral leptomeningeal vascular malformations and cerebral atrophy. In the complex combined low-flow vascular malformation, KTS, the capillary malformation commonly affects a lower extremity. The diagnosis of a capillary malformation is clinical, and no imaging is required to diagnose it. Treatment of capillary malformations is for cosmetic appearance; flash-lamp pulsed dye laser therapy is the treatment of choice.¹⁶ There is no role for interventional radiology or surgery in the treatment of capillary malformations.

Common (Cystic) Lymphatic Malformation

Common (cystic) lymphatic malformations are made up of cysts containing lymphatic fluid that are low flow and are classified as macrocystic, microcystic, or mixed cystic lymphatic malformations.¹⁷ Although the definition of macrocysts and microcysts remains undecided, a good practical definition is based on macrocysts having cavities visible on imaging, whereas microcysts appear as “solid” tissue with cysts seen only histologically. However, some consider macrocysts as those cysts greater than 1 cm in diameter and microcysts as less than 1 cm. Outdated terminology, such as *cystic hygromas* and *lymphangiomas*, should no longer be used, because they imply “tumor.”

Common (cystic) lymphatic malformations often present as localized, sometimes infiltrative masses, although some can present with fluid leakage, such as chylous fluid in body cavities or weeping from skin vesicles (Fig. 13-20). The cystic type of lymphatic malformations are usually noted at birth; however, they can be seen at any age, including prenatally on imaging. Although skin and soft tissues (subcutaneous and fascial planes in muscle) are most commonly affected, lymphatic malformations can involve bone and more rarely viscera such as the gastrointestinal tract and lungs. The axillary, thoracic, cervicofacial, mediastinal, retroperitoneal, buttock, and anogenital regions are commonly affected. Soft tissue and skeletal hypertrophy can occur with lymphatic malformations. Macrocystic lymphatic malformations appear as soft, partially compressible masses. Macrocystic lymphatic malformations, unlike common venous malformations, show no increase in size or dependency and no refilling after compression is released. Lymphedema can occur if there is diffuse infiltration of subcutaneous tissues. Interestingly, infection and

Fig. 13-20 Clinical features of cystic lymphatic malformations. Typical findings in five patients. **A**, Newborn with large, cervical, partially compressible macrocystic lymphatic malformation. **B** and **C**, Newborn with a large mixed cystic lymphatic malformation.

Continued

Fig. 13-20, cont'd **D**, Microcystic lymphatic malformation of the skin (sometimes referred to as *lymphangioma circumscriptum*) with recurrent bleeding from skin lesions. **E**, Firm, noncompressible expansion of the wrist with bruising (from spontaneous intralesional hemorrhage) in a microcystic lymphatic malformation (the same patient is shown in ultrasonography scan in Fig. 13-6, *B*, and in MRI scan in Fig. 13-7, *D-F*). **F** and **G**, Extensive subcutaneous microcystic lymphatic malformation in the upper extremity, shoulder, and chest wall.

intralesional bleeding can occur in all types of cystic lymphatic malformations; this sometimes leads to alarming expansion of the lesion with pain and a red/blue skin discoloration.

The problems associated with cystic lymphatic malformations can frequently be related to their location, such as proptosis from periorbital lymphatic malformations, airway obstruction in cervicofacial lymphatic malformations, oozing of fluid and bleeding from cutaneous and lingual lymphatic malformation vesicles, and protein-losing enteropathy in gastrointestinal tract disease. Lymphatic malformations of the extremities can be associated with overgrowth and limb-length discrepancy. In *Gorham-Stout disease* (soft tissue and skeletal lymphatic malformations leading to progressive osteolysis), pathologic fractures and vertebral instability can occur.

Imaging of Cystic Lymphatic Malformation

Cystic lymphatic malformations are best imaged by ultrasonography and MRI⁴ (see Figs. 13-6 and 13-7), particularly before starting treatment. Imaging determines the macrocystic and microcystic disease and helps in treatment planning. MRI better documents the full extent of deeper, larger, and more complex lymphatic malformations; however, ultrasonography can answer many questions before treatment for many patients. Macrocystic structures are easily visible on ultrasonography and MRI, especially when cysts are larger than 1 cm in diameter. Microcystic lymphatic malformations appear as predominantly solid lesions with no identifiable cysts on imag-

ing. Cystic lymphatic malformations on MRI appear hypointense on T1 and hyperintense on T2 (because of high water content). Macrocystic lymphatic malformations show septal contrast enhancement, whereas microcystic lymphatic malformations show either no contrast enhancement or ill-defined enhancement of the entire lesion. Fluid-fluid levels in cysts are caused by layering of protein or blood. Enlarged or anomalous venous channels can sometimes be seen in close proximity to cystic lymphatic malformations. Contrast lymphangiography is not required for patients with cystic-type lymphatic malformations; however, contrast lymphangiography is useful in selected lymphatic malformations in which there are abnormal lymphatic channels and leaks of the thoracic duct and in patients with chylous effusions.

Treatment of Cystic Lymphatic Malformation

The indications for treatment of cystic lymphatic malformations include troublesome symptoms with recurrent swelling, pain, infections, functional impairment, leakage of fluid and bleeding from the lymphatic malformation, and cosmesis. Spontaneous intralesional bleeding causes sudden enlargement of cystic lymphatic malformations and is treated conservatively. Analgesics should be given for pain. Lymphatic malformation enlargement occurring with systemic viral or bacterial infections usually resolves without specific treatment. Bacterial infections occurring in the lymphatic malformation resulting in a cellulitis-like presentation with reddening, enlargement, hardening, and pain requires appropriate antibiotics (often intravenous), analgesics, and hospital admission. Some patients with frequent recurrent infections of their lymphatic malformation should be considered for long-term prophylactic antibiotics. Chronic pain in those patients with extensive disease requires expert management.

Other treatment options include injection sclerotherapy, surgical interventions, laser techniques, conservative measures, and combinations thereof.^{18,19} Recently, medical therapy with rapamycin and sildenafil has been suggested for selected patients.^{20,21} Rapamycin is now used in patients with complicated vascular anomalies when there is a lymphatic component and particularly when there are no other/limited treatment options.²¹ Macrocystic lesions can be treated through sclerotherapy or resection with excellent results in nearly 90% of patients.^{19,22} The advantages of sclerotherapy over surgical resection for macrocystic lymphatic malformations includes the avoidance of surgical scars, reduced risk of neurovascular injury, and when the disease is present in challenging anatomic locations, uneventful recoveries in most patients (Figs. 13-21 and 13-22).

Fig. 13-21 Injection sclerotherapy and drainage procedure for large cervicothoracic macrocystic lymphatic malformations. **A** and **B**, Large lymphatic malformation distorting the thoracic cavity.

Continued

Fig. 13-21, cont'd C and D, Ultrasonographic guidance used to puncture cysts. E, Larger cysts drained and cysts aspirated before sclerosant injection. F, Contrast injected through drains to outline cysts before sclerosant injection. We no longer inject contrast for such routine cases.

For well-localized macrocystic lymphatic malformations, sclerotherapy can be curative (see Fig. 13-22), and at least 90% of patients with macrocystic lymphatic malformations will significantly improve. Diffuse and predominantly microcystic lymphatic malformations are difficult to eradicate, although sclerotherapy can offer some reduction in lesion size, depending on the number of cysts that can be injected.¹⁹

When only a few cystic cavities are seen on ultrasonography in a microcystic lymphatic malformation that is predominantly “solid” on ultrasonography, we would not routinely offer injection sclerotherapy. Surgical resection of complex and microcystic lymphatic malformation can be beneficial and usually needs to be well planned and staged. The postsurgical recurrence rate, however, for microcystic lymphatic malformations is approximately 40% and is the result of regrowth and/or reexpansion of residual disease. Multiple scars from many surgeries are not uncommon, which themselves can lead to problems. Microcystic lymphatic malformations that were deep to the skin before surgery can grow externally along scars after surgery. It has been suggested that sclerotherapy of the resection cavity may help to reduce the recurrence of disease. Injection sclerotherapy can also help temporarily to control weeping or bleeding from cutaneous vesicles.

It has been difficult to compare treatment outcomes from surgery and injection sclerotherapy. Surgical results to date have been based on cosmetic appearances, without postsurgical imaging to assess deep residual disease.

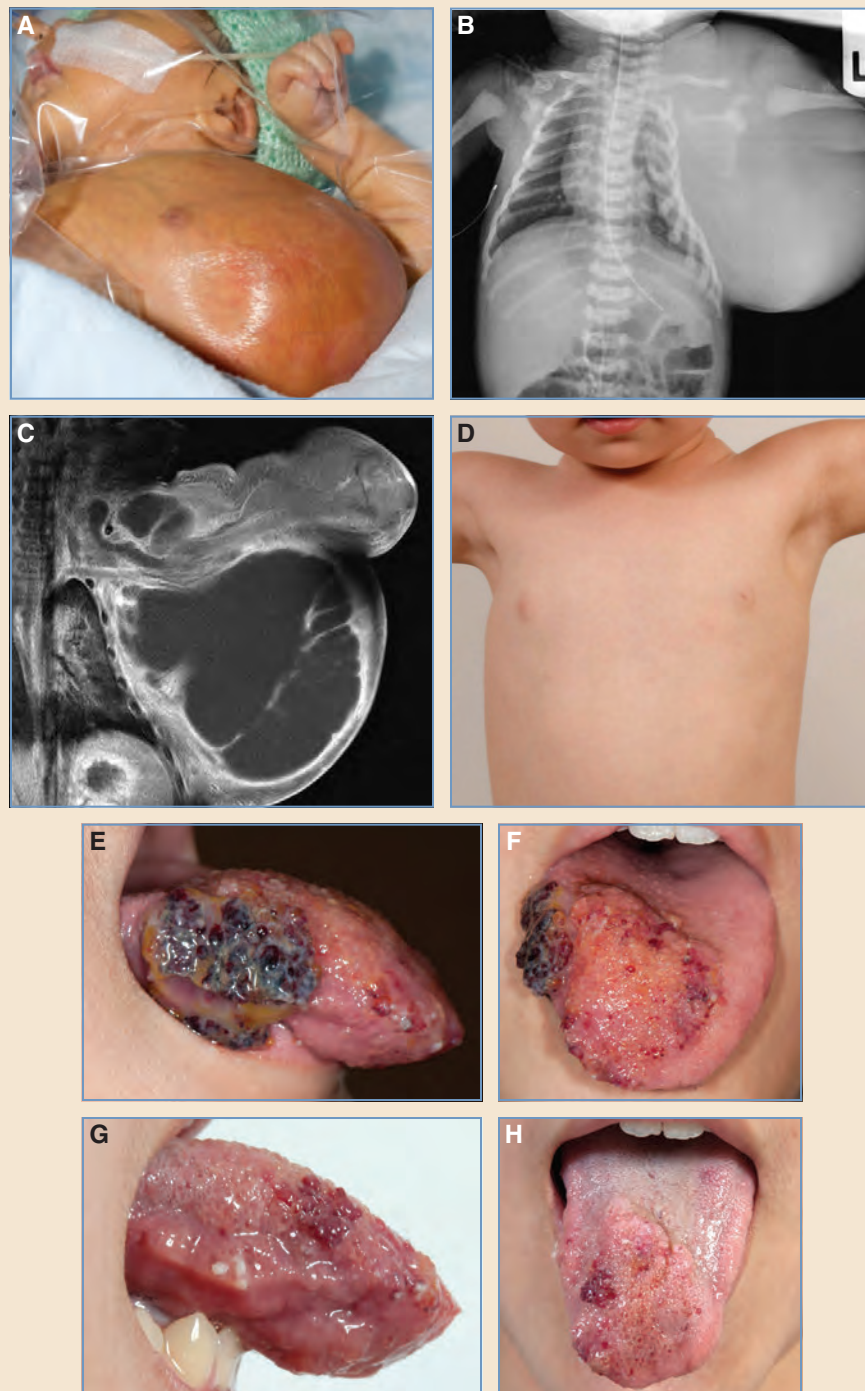

Fig. 13-22 Results of lymphatic malformation sclerotherapy for macrocystic lymphatic malformation and microcystic lymphatic malformation. **A-D**, Excellent results for macrocystic disease can be expected with administration of doxycycline. This infant with a large thoracic macrocystic lymphatic malformation had complete resolution after sclerotherapy using small drainage catheters, with no disease residue clinically on imaging. **E-H**, Lingual microcystic disease can be improved with bleomycin. After direct bleomycin injection into the tongue of this patient, there was no recurrence of bleeding, and many tongue surface vesicles regressed.

Cystic Lymphatic Malformation Sclerotherapy

Most injection sclerotherapy procedures are performed with ultrasonographic guidance (see Fig. 13-21). When sclerosing macrocysts, the cysts are aspirated and then sclerosant is injected. In our practice, for macrocysts greater than 5 cm diameter, we place small drains (5 Fr) into these larger cysts, aspirate fluid, and then inject sclerosant (see Fig. 13-21). Drains are opened after 6 hours, and repeat sclerosant injection is performed through the drain the following day before drain removal. Fluoroscopic guidance is rarely needed unless drains are placed. CT guidance may be required when drains are placed in challenging locations, such as the mediastinum and other intrathoracic locations, and for intraosseous disease. When sclerosing microcysts, it may be impossible to direct the needles into very small cysts, because often there are no cyst cavities visible. Therefore the sclerosant is injected throughout the entire lesion.

The dose of sclerosant injected into the lesion depends on the aspirate volume when treating macrocysts or the overall size of the lesion when treating microcystic disease. There are several useful sclerosants for treating cystic lymphatic malformations (Box 13-3).

Bleomycin has been shown to be effective in many patients with lymphatic malformations.²³⁻²⁸ It is associated with significantly less swelling after injection compared with other sclerosants; therefore bleomycin has a significant advantage when administered to treat lesions in the orbit, tongue, and airway (see Fig. 13-22). Dosage has been a concern with bleomycin; however, for sclerotherapy, low intralesional doses are used compared with the significantly higher systemic dosage used for chemotherapy. In our practice we restrict the use of bleomycin for treating macrocystic and microcystic lymphatic malformations of the tongue, orbit/eyelid, and airway.

After sclerotherapy, some swelling of the treated area is expected. Significant pain is unexpected and managed appropriately. Complications are unusual and unexpected after lymphatic malformation sclerotherapy. Infrequent self-limiting minor bleeding can be seen in the treated cyst or cysts during the procedure or shortly thereafter. Rarely local skin blistering is seen with doxycycline and occurs with overfilling of superficial cysts.

Most lymphatic malformation sclerotherapy is performed as an elective day-case procedure with a 4-hour postprocedure stay. Overnight or intensive care admission may be required and arranged as necessary before treatment. At discharge, the patient should be systemically well

Box 13-3 Sclerosants for Treating Cystic Lymphatic Malformations

For Macrocystic Lymphatic Malformations

- Doxycycline solution is used in a 10 mg/ml concentration in sterile water, with a maximum patient dose between 300 mg for babies and 1200 mg for children 12 years of age and older. Half the volume of cyst aspirate is replaced with doxycycline solution.
- 3% STS liquid is used to irrigate larger macrocysts (greater than 5 cm) before doxycycline injection. The maximum dose of STS is 0.5 ml/kg body weight.
- Ethanol or dehydrated alcohol 100% is our second-line sclerosant after doxycycline for macrocysts. The maximum patient dose is 1 ml/kg.

For Microcystic Lymphatic Malformations

- Bleomycin is used for those patients with solid disease on imaging in selected locations (tongue, eyelid, orbit, or airway) in a concentration of 1 mg/ml. A suggested maximum patient dose is 0.5 mg/kg for neonates and 1 mg/kg or 15 mg (15 units) for older patients.
- Doxycycline (as above), only if small cystic cavities visible on ultrasonography can be injected.

with no concerns regarding the treatment site other than expected swelling and occasional skin bruising. Intralesional sclerotherapy results in scarring and cyst collapse and may need to be repeated at 6-week intervals. Arrangements should be made for appropriate posttreatment clinical and imaging follow-up.

Venous Malformation

Venous malformations are the most frequent type of vascular malformation referred to vascular anomaly clinics and the “common type” are the most frequent venous malformations treated by pediatric interventional radiologists. They are low-flow lesions and consist of sinusoidal venous spaces with thin walls, abnormal smooth muscle cells, and variable communications with adjacent veins. In a *glomovenous malformation* (GFM, a variant of venous malformation), the vascular channels are lined by glomus cells.²⁹ Venous malformations can arise anywhere in the body and may involve all tissue planes (Fig. 13-23).

Fig. 13-23 Clinical features of common venous malformation. Four patients with typical physical findings. **A**, Large periscapular venous malformation with blue compressible swelling and a network of dilated veins. **B**, Venous malformation of the hand with blue compressible swelling of the palm and the second through fifth fingers. The hand swellings were reduced in size through compression/arm elevation and increased in size on release of compression/placement of the limb in a dependent position. **C**, Diffuse venous skin stain of the lower extremity signaled diffuse intramuscular venous malformation throughout the leg. **D**, Reduced girth of the right leg from a diffuse intramuscular venous malformation in the thigh and calf is associated with osteoarticular disease of the knee joint. There is no skin stain in the affected leg in this patient.

Fig. 13-24 Orocerivopharyngeal venous malformation. **A**, A teenage girl with hemoptysis from a right-sided oropharyngeal venous malformation. Clinical examination showed obvious right-sided blue venous malformation. The full extent of the disease was not appreciated until the MRI scan was done, because she had no symptoms related to her neck and no cervical abnormality on physical examination. **B** and **C**, MRI showed an extensive soft tissue venous malformation in the oropharynx abutting the airway, with intramuscular extension throughout the right neck.

Venous malformations are often seen in the skin and soft tissues.^{4,30} Forty percent of them affect the head and neck, 40% affect the extremities, and the remainder affect the trunk. Visceral involvement can occur. They grow in proportion to the patient and show no regression. Venous malformations may be evident at birth or more commonly become apparent and sometimes symptomatic with pain and swelling later in childhood. Their appearance is variable, including varicosities, phlebectasias, discrete spongy masses, or complex channels permeating tissues and organs (Figs. 13-24 and 13-25). Most occur sporadically and are unifocal, although some are multifocal or diffuse. Diffuse venous malformations commonly affect an entire extremity with much muscle and large joint involvement, particularly the knee joint (see Fig. 13-25). On physical examination, they appear as soft, bluish, compressible lesions, showing refilling with release of compression and increasing in size with dependency or during a Valsalva maneuver. As many as 42% of patients with a venous malformation have a localized intralesional coagulopathy, which is severe in approximately 4% and seen particularly in those with diffuse intramuscular involvement, where significant elevated D-dimer and low fibrinogen levels can be detected in peripheral blood.³¹⁻³³ Intralesional thrombosis occurs and is sometimes associated with acute pain. Muscle wasting is evident in those with diffuse disease. Involvement of bones and joints may lead to pathologic fractures, recurrent hemarthroses and arthritis with osteoarticular changes similar to hemophilia (see Fig. 13-25). In patients with a diffuse type of venous malformation, pulmonary hypertension has been recently reported. However, it is unclear if this is caused by recurrent silent pulmonary emboli.³⁴

Venous malformations, which are often multiple, can occur throughout the gastrointestinal tract. Venous malformations of the pelvis and perineum are associated with venous malformations in the descending colon and rectum. Gastrointestinal bleeding, typically chronic, can cause anemia. In blue rubber bleb nevus syndrome, multifocal venous malformations are seen in the skin (typically on the palms of the hands and soles of the feet) and soft tissues, in addition to the gastrointestinal tract. The diagnosis of gastrointestinal involvement is best made by endoscopy, including wireless capsule endoscopy. If bleeding is problematic, surgical and endoscopic treatment options should be considered for gastrointestinal venous malformations.

Fig. 13-25 Diffuse lower extremity venous malformation. **A-C**, T2-weighted MRI sequences show diffuse intramuscular involvement throughout the lower extremity with intraarticular venous malformation. **D**, Cruciate ligaments are enveloped by the articular venous malformation. **E**, Gradient echo MRI sequence shows hemarthrosis. Hemosiderin appears as artifact with black areas of signal loss on gradient echo sequences. **F**, Severe arthropathy can result from recurrent hemarthroses.

Imaging of Common Venous Malformation

Common venous malformations are best imaged by ultrasonography and MRI⁵ (see Figs. 13-4 and 13-5). Ultrasonography can assess superficial and focal lesions. Ultrasonography typically shows a localized lesion with anechoic channels that are compressible and show refilling with release of pressure. Variable solid elements in the lesion and sometimes hyperreflective phleboliths (calcified thrombi) with acoustic shadowing can be seen on ultrasonography. MRI is highly tissue specific, with T1 hypointensity, T2 hyperintensity, and nonuniform lesional enhancement after contrast. The T2 hyperintensity is caused by slow-flowing blood in the venous malformation. The T1 intralesional high signal is caused by thrombi. Phleboliths within venous malformations are seen as signal voids on T2 imaging. Phleboliths distinguish venous malformations from tumors and all other vascular malformations. The pattern of contrast enhancement distinguishes venous malformations from cystic lymphatic malformations. MRI shows the full extent of the venous malformation, because there may be significant disease not evident by clinical examination

(see Figs. 13-23 and 13-24). In patients with diffuse extremity disease, MRI is needed to assess intraarticular involvement, and to evaluate the full extent of the disease (see Fig. 13-24).

Invasive venography is not required before treatment. Direct percutaneous puncture venography is performed at the time of injection sclerotherapy. If conventional venography of functional veins is required, it can be performed at the time of sclerotherapy.

Treatments of Common Venous Malformation

The indications for treatment include troublesome symptoms with pain, swelling, functional impairment, bleeding (hemarthroses, gastrointestinal, and genitourinary), and cosmesis. Treatment options include injection sclerotherapy, laser techniques (usually endovenous), surgical interventions (excision and partitioning), endoscopic treatments, conservative measures, and combinations thereof.³³ Combining sclerotherapy with surgical techniques can be advantageous in selected patients.

Direct puncture intralesional sclerotherapy is the mainstay of treatment for many common venous malformations.^{4,35,36} However, if the venous malformation is small, focal, and superficial, surgical excision may be preferable. When postinjection surgical excision is planned, glue injection into venous malformations is an alternative to sclerosant injection.³⁷ Sclerosants cause an intense early inflammatory response that can potentially be challenging for the surgeon.

For diffuse venous malformations of the extremities, conservative management with graded compression stockings can achieve significant symptom improvement if they are correctly fitted, deliver adequate compression, are worn daily, and are replaced regularly (three to four times per year). It is now recommended that early surgery be performed in patients with intraarticular venous malformation, even if asymptomatic, to remove the articular venous malformation and prevent joint destruction.³⁸ In patients with troublesome pain from intralesional thrombosis (where D-dimer levels are elevated greater than three times normal), low-molecular-weight heparin can be considered and needs to be given by subcutaneous injection twice daily for several weeks, which often results in excellent pain relief. Compression garments can improve the abnormal coagulation indices.

Patients with facial venous malformations are commonly present for sclerotherapy treatment because of disfigurement, whereas those with extremity venous malformations are usually treated because of pain. Although most venous malformation treatment is not curative, many patients gain symptomatic relief. Most published series document improvement in pain after sclerotherapy.^{39,40} As many as 90% of patients expect to see some reduction of pain. However, it is well recognized that pain tolerance differs among patients. The worst outcomes for pain improvement after sclerotherapy are in patients with venous malformations involving an entire muscle or muscle compartment.

Common Venous Malformation Sclerotherapy

Preprocedural blood is drawn to establish D-dimer and fibrinogen baseline levels, and this should be performed in all patients, especially those with diffuse venous malformations. If the fibrinogen level is less than 1 g/L, low-molecular-weight heparin is required before treatment to improve the effectiveness of sclerotherapy and reduce intraprocedural bleeding. It is important to be aware that both sclerotherapy and surgical excision of common venous malformations can change a preexisting localized intralesional coagulopathy into a disseminated intravascular coagulopathy with potential life-threatening bleeding.

Most procedures are performed with ultrasonographic guidance (Fig. 13-26). If sclerotherapy is limited to small cutaneous channels, direct puncture without image guidance may be sufficient. CT guidance is rarely needed for venous malformation sclerotherapy unless challenging loca-

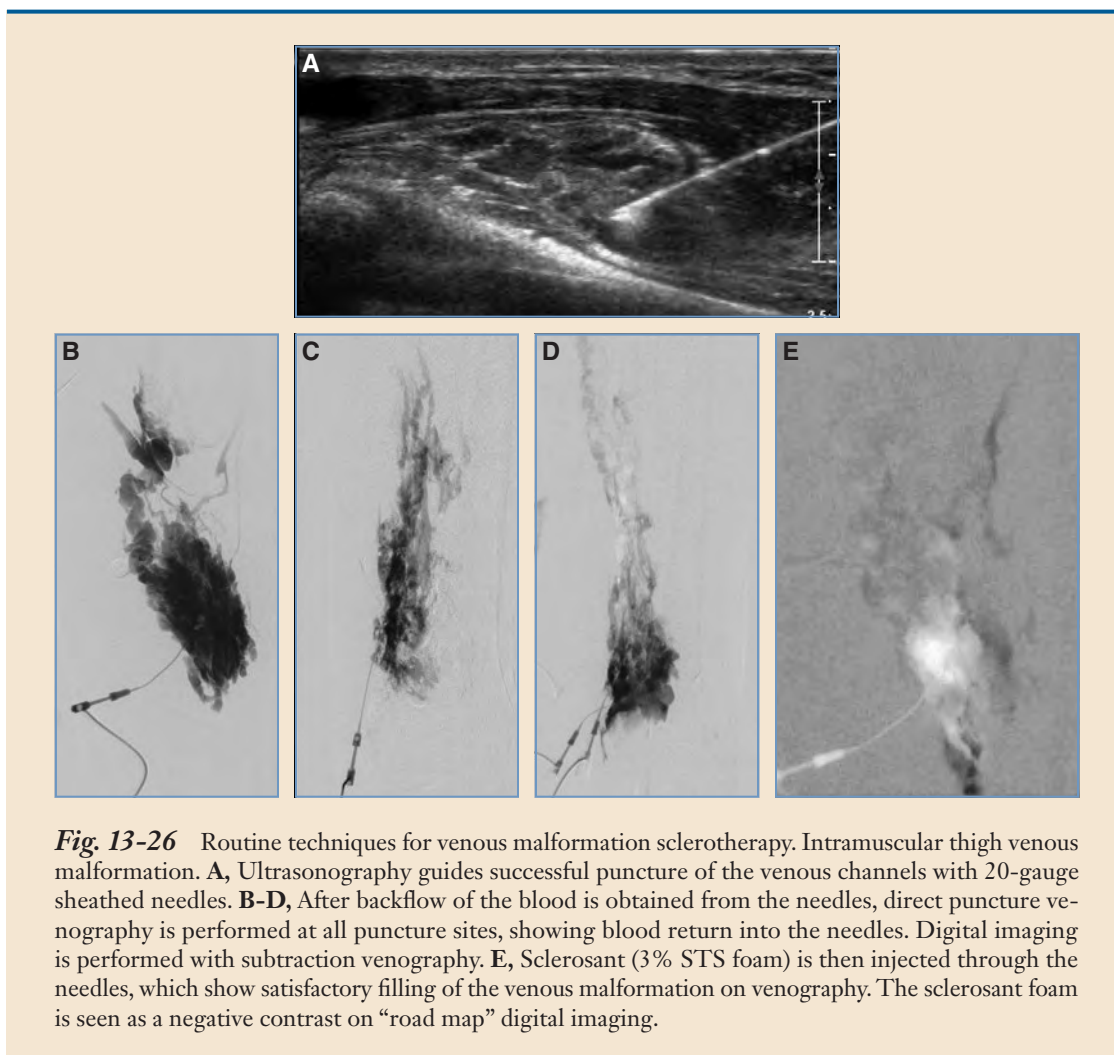

Fig. 13-26 Routine techniques for venous malformation sclerotherapy. Intramuscular thigh venous malformation. **A**, Ultrasonography guides successful puncture of the venous channels with 20-gauge sheathed needles. **B-D**, After backflow of the blood is obtained from the needles, direct puncture venography is performed at all puncture sites, showing blood return into the needles. Digital imaging is performed with subtraction venography. **E**, Sclerosant (3% STS foam) is then injected through the needles, which show satisfactory filling of the venous malformation on venography. The sclerosant foam is seen as a negative contrast on “road map” digital imaging.

tions are treated, which may occur with mediastinal, intrathoracic, or intraosseous disease. To enlarge a venous malformation of the extremity to aid in puncture, an external tourniquet is applied immediately above the venous malformation and is always removed before venography and sclerosant injection. The venous malformation is punctured, with appropriate multiple needles placed throughout the venous malformation (see Fig. 13-26; Fig. 13-27). Direct puncture venography performed at each puncture site should show satisfactory filling of the malformation, and then sclerosant is injected at suitable sites (see Fig. 13-26).

Sclerosing agents used for intralesional sclerotherapy into venous malformations include 3% STS foam, ethanol, and bleomycin. STS and ethanol cause endothelial damage, thrombosis, scarring, and a reduction in the size of the venous malformation. However, 3% STS has gained popularity, because intraoperative fatalities and major systemic complications are associated with ethanol. The maximal doses at any one treatment should not exceed 0.5 ml 3% STS liquid or 1 ml ethanol/kg body weight. STS can be easily made into a foam by agitating an equal volume of liquid and air. Potential complications associated with the use of STS and ethanol are covered in Box 13-4.

Fig. 13-27 A, Combined surgical partitioning and injection sclerotherapy of a soft tissue venous malformation. Prominent upper lip venous malformation. B and C, The venous malformation was partitioned by suturing the lesion with Vicryl sutures. D, Multiple 23-gauge butterfly needles were then placed throughout the partitioned venous malformation. Good backflow of blood was obtained from all needles, direct puncture venography was performed, and sclerosant injected with 3% STS foam and bleomycin. Partitioning reduced the overall size of the venous malformation and thus less sclerosant was used. E, An excellent result was achieved after only two treatments.

Box 13-4 Potential Complications Associated With Ethanol and Sodium Tetradecyl Sulphate Sclerotherapy

- Sclerosant effects
 - Local tissue injury (blisters, tissue necrosis, neurologic injury and paralysis, compartment syndrome)
 - Hemoglobinuria
 - Venothromboembolic events
 - Metabolic complications (for example, acidosis, hypoglycemia)*
 - Cardiorespiratory events (respiratory depression, cardiopulmonary collapse, arrhythmias)*
 - Seizures*
 - Perilesional fibrosis (muscle)
- Coagulation derangement
- Procedure plus device risk (from catheters and implantable devices, such as embolic and occlusion devices)
- Inadvertent embolization (of blood clots and embolic agents)
- Age-related risk (such as CNS susceptibility to alcohol in neonates)*

*Sclerosant effects observed with alcohol, whereas all other effects can be seen with both sclerosants.

Major complications are rarely encountered when treating venous malformations; however, sclerotherapy is not without risk. The local risk of tissue injury and compartment syndrome may be seen with STS and ethanol. Occasional closure of large venous channels within the venous malformation or draining the venous malformation can be performed with coils, glue, and endovenous laser ablation. Combining surgical partitioning of a venous malformation with sclerotherapy reduces the amount of sclerosant needed to fill the venous malformation (see Fig. 13-27).

In our practice we have reserved bleomycin for common venous malformations in locations in which postprocedure swelling may be problematic (for example, orbit/eyelids, lips, and tongue, or oral cavity, including the tongue and airway). To reduce washout of bleomycin when injected into venous malformations, a small volume of 3% STS foam is injected immediately before the bleomycin, which results in lesional thrombosis and stasis.

After sclerotherapy, local swelling begins immediately and progresses over several hours (eventually subsiding by 5 to 7 days).⁴¹ Tissue swelling is expected and does not preclude discharge. Pain should be managed appropriately. Significant pain after STS is unexpected. Skin and mucosal blistering is not uncommon when these locations are treated and can be seen before the patient leaves the procedure room or within 24 hours of the injection. Polysporin ointment should be used on skin blisters for 1 week after treatment. Tissue ulceration may occur, although rarely, and should be managed appropriately in conjunction with plastic surgery. Hydration is important after the procedure to minimize the effects of hemoglobinuria, which frequently occurs with STS/ethanol.⁴² Oral fluids are encouraged, along with twice normal IV fluid maintenance given routinely for 4 hours after the procedure. Hemoglobinuria is managed by additional hydration with IV and oral fluids, intravenous furosemide, and occasional urine alkalinization with a sodium bicarbonate intravenous infusion. Measuring urine output and observing urine color during the hospital postprocedural stay is important. All complications require close observation and follow-up⁴³ (Table 13-1).

Most venous malformation sclerotherapy is performed as an elective day-case procedure with a 4- to 6-hour postprocedure stay. Overnight or intensive care admission may be required and arranged as necessary before treatment. In patients with a venous malformation involving an entire extremity requiring sclerotherapy to multiple locations, consecutive daily treatments over 2 to 3 days can be performed if the same location is not treated more than once over the 2 to 3 days. At discharge, the patient should be systemically well, with no concerns regarding the treated site other than the expected swelling and occasional skin blistering.

Common venous malformations have a propensity for recanalization and reenlargement. Therefore repeat injection sclerotherapy treatments are needed in many patients. Staged sclerotherapy is required, and this can be performed, for example, every 6 weeks. Arrangements are made for appropriate clinical and imaging follow-up after treatment.

Table 13-1 Schobinger Clinical Severity Score of Peripheral Arteriovenous Malformations

Stage	Title	Clinical Features
I	Quiescent stage	Warm vascular stain in skin mimicking a capillary malformation
II	Expansion stage	Lesion warmer, bruits and thrills are present, lesion is enlarging
III	Destructive stage	Ulcers, hemorrhage, bone lysis, and pain
IV	Cardiac decompensation stage	Onset of cardiac failure from overload

Fig. 13-28 Outcome after sclerotherapy of labial and lingual venous malformation. After sclerosant injection with small doses of 3% STS foam and bleomycin, good results were seen in these three patients, with no major complications and only mucosal blistering in patient A (clinical follow-up between 3 and 5 years).

Fig. 13-29 Outcome after sclerotherapy of small eyelid venous malformation. Sclerosant injection with small doses of 3% STS foam and bleomycin resulted in good clinical improvement.

Improvements in pain and disfigurement are expected in most patients undergoing sclerotherapy (Figs. 13-28 and 13-29). Clinical improvements in pain reduction, however, do not always correlate with a reduction of lesion size on imaging. In our practice, we do not perform routine posttreatment imaging unless symptoms persist despite adequate treatment or if further treatment is required for recurrent problems.

Arteriovenous Malformation

Arteriovenous malformations (AVMs) are high-flow vascular malformations, which are very different compared with the more common low-flow vascular malformations.⁴ This section refers to peripheral AVMs and not AVMs involving the central nervous system. An AVM is characterized by an abnormal arteriovenous precapillary shunt, the so-called *nidus*. The nidus differentiates AVMs from congenital AVFs, which are high-flow vascular malformations with precapillary shunts with no nidus. Often multiple arteriovenous shunts are present in AVMs and AVFs. These shunts can be localized or extensive and commonly involve the extremities, trunk, and viscera. AVMs do not respect tissue boundaries, and AV shunting can occur in soft tissues and bone. AVMs usually undergo slow progression and expansion over many years, and during childhood the AVM grows in proportion with the child. The expansion seen in extracranial AVMs is the primary cause of the morbidity associated with these lesions. The Schobinger staging (see Table 13-1) is a clinically based severity scoring system and should be used for all peripheral AVMs (Fig. 13-30).

Fig. 13-30 Clinical features of peripheral AVM. **A**, Schobinger stage I AVM: red vascular skin stain on forehead of an infant. The lesion was warm and pulsatile, and Doppler ultrasonography showed marked hypervascularity with arteriovenous shunts in subcutaneous tissue beneath the stain. **B** and **C**, Schobinger stage II AVM: a warm distal extremity, prominent veins, and palpable thrill from a radial artery aneurysm. **D-F**, Schobinger stage III AVMs: dystrophic skin and mucosal changes from tissue necrosis with ulceration on the pinna and maxillary destruction and bleeding (different patients).

At birth, AVMs appear as a pink cutaneous skin stain and can be mistaken for a capillary malformation or the premonitory sign of an infantile hemangioma (see Fig. 13-30). However, high flow from arteriovenous shunting is present beneath the vascular skin stain, and this can easily be detected with Doppler ultrasonography. The high flow is characterized clinically by increased growth and warmth of the affected body part, bruits, thrills, arterial aneurysms, and enlargement of draining veins (see Fig. 13-30). These features become progressively evident throughout childhood. Arteriovenous shunting can be confirmed by the use of continuous wave Doppler imaging. Tissue ischemia from arteriovenous shunting results in pain and tissue necrosis with ulceration and bleeding (see Fig. 13-30). High-output cardiac failure can be seen in patients with large, extensive AVMs.

Regarding the natural progression of extracranial AVMs, it has been found that as many as 44% of children with Schobinger stage I disease will progress before adolescence and up to 83% before adulthood.⁴³ AVM progression is more likely to occur during adolescence, and diffuse AVMs are more likely to expand in childhood and puberty compared with localized AVMs.⁴³

Local trauma (including iatrogenic trauma) can trigger rapid expansion in these lesions, with increased shunting. Proximal surgical ligation or proximal arterial embolization of feeding arteries will result in the arteriovenous shunts recruiting a vascular supply from adjacent territories. There is still debate whether pregnancy affects AVM progression.

Imaging of Arteriovenous Malformation

AVMs are best imaged noninvasively by MRI, including MRA.⁴⁴ Inflow arteries are enlarged, tortuous, and sometimes aneurysmal. Outflow veins are enlarged and tortuous. Numerous flow voids are evident on spin-echo sequences because of the high flow in arterial channels, and the high density of vessels is easily demonstrated, including the nidi. MRI provides an excellent overall map showing the distribution of the disease and the tissues involved with the shunts. On MRI and ultrasonography, there is no evidence of a parenchymal tumor, which allows differentiation from vascular tumors, some of which have arteriovenous shunts. Soft tissue edema in AVMs can be seen on MRI surrounding the arteriovenous shunts.

It is important to assess the surrounding soft tissue around an AVM. AVMs located in large fatty areas can occur in *PTEN* gene mutation–related AVMs (for example, in *Banyan-Riley-Ruvalcaba* syndrome). However, details of feeding arteries, shunt morphology, and venous drainage are better assessed by catheter angiography and direct puncture techniques (Fig. 13-31).

Catheter angiography remains the benchmark procedure in imaging; however, it is not required until treatment is needed and is usually performed at the time of the first embolization. For example, the first catheter angiogram on a patient with a peripheral AVM should include “global” and “selective” angiography (see Figs. 13-9 and 13-31). Diagnostic angiography should always try to demonstrate the following:

- Arterial runoff throughout the affected extremity
- Feeding arteries to shunts
- Location of the shunts
- Shunt morphology
- Venous drainage from the shunts (see Figs. 13-9 and 13-31)

Carefully studying the angioarchitecture can help to plan endovascular treatment.⁴⁵

Fig. 13-31 Catheter angiography demonstrating arteriovenous shunts (nidi) in an upper extremity AVM. **A**, Global catheter angiography can show arteriovenous shunts/nidi in the forearm and hand. Detailed angiography is needed to fully evaluate arteriovenous shunts by selective catheterization of the interosseous, radial, and ulnar arteries. **B**, Interosseus artery. **C**, Radial artery. **D**, Ulnar artery.

Treatment of Arteriovenous Malformation

Many patients are observed with AVMs in the early stages and are monitored carefully throughout childhood. Most AVMs will eventually require treatment because of continued lesion expansion. Lesion expansion can be associated with troublesome symptoms, including tissue ischemia and ulceration, pain, and sometimes cardiac overload.⁴ Although the ultimate treatment goal is complete shunt occlusion and surgical resection, this goal cannot always be achieved.

The mainstay of treatment to date has been endovascular treatments with catheter embolization and sometimes surgery. Endovascular treatments with catheter embolization can at best provide control and do not cure the AVM. Although embolization, either alone or in combination with surgical excision, has been the primary treatment for many, it has recently been suggested that well-localized stage I AVMs that are amenable to surgical excision have better outcomes without preoperative embolization.^{43,46,47} However, the full extent of the AVM may be underrecognized during early disease; therefore embolization and surgery during infancy and early childhood are rarely performed because of the high risk of disease progression. Embolization and resection produce a proangiogenic environment, resulting in lesion enlargement. Disease recurrence is high after treatment and is reported in up to 93% of cases.⁴³ This propensity for progression or recurrence after certain treatments poses many challenges, which are compounded by the high risk from treatment.⁴⁶⁻⁴⁹ There is no “quick fix” for treating AVMs, and most require repeated treatment sessions over several years. When surgical resection is performed after embolization, surgery should be performed within a few days of the embolization. Embolization can decrease intraoperative bleeding; however, it does not reduce the amount or extent of tissue that must be resected. Embolization alone can be useful for symptom control in patients with extensive disease when no other suitable treatment options are available (Fig. 13-32). Surgical amputation may be considered for advanced extremity AVMs that cause major problems threatening the affected limb or the patient’s life (see Fig. 13-32).

Cures are rarely seen, and all patients require long-term follow-up after treatment. Interestingly, AVMs that fail to show reexpansion for 5 or more years after intervention are more likely to have long-term control.⁴³

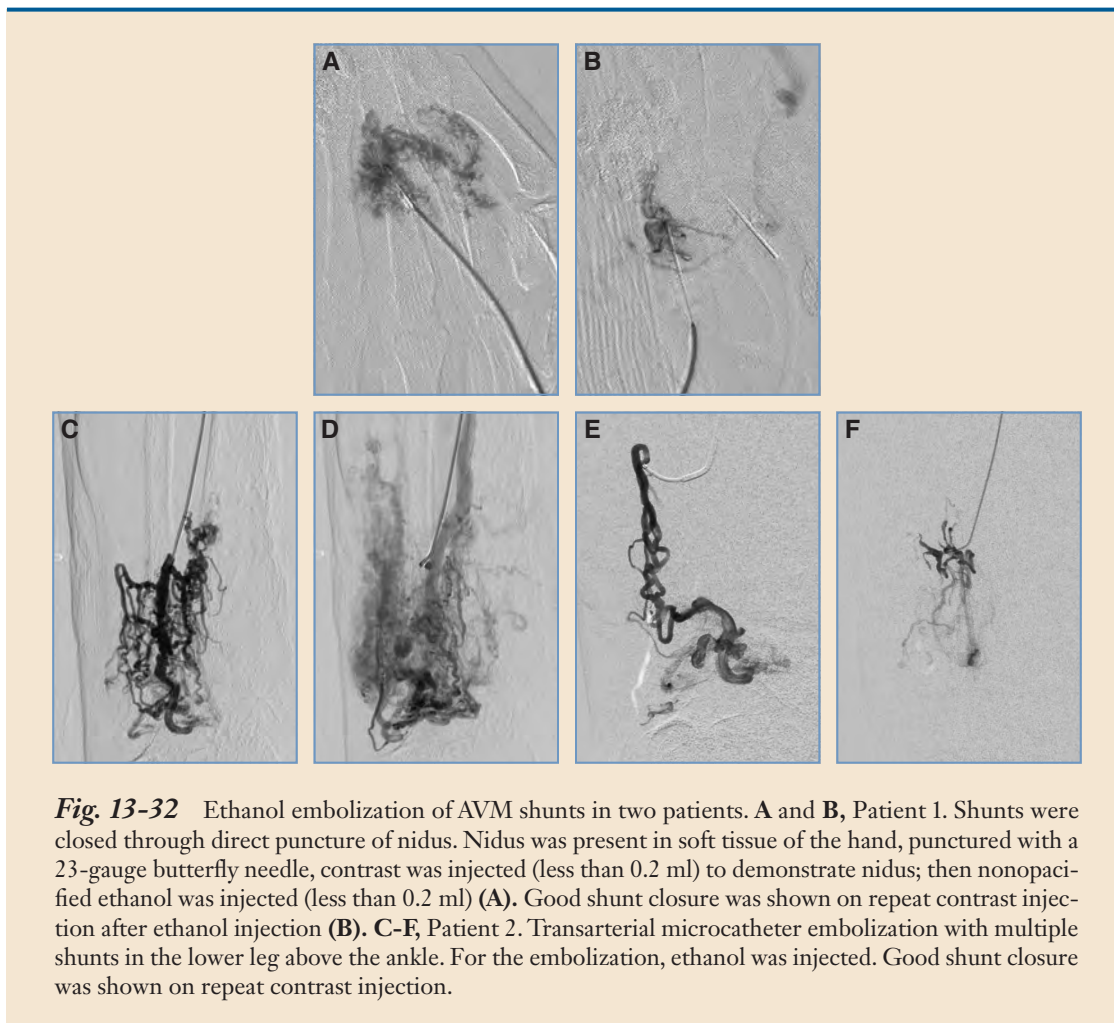

Fig. 13-32 Ethanol embolization of AVM shunts in two patients. **A** and **B**, Patient 1. Shunts were closed through direct puncture of nidus. Nidus was present in soft tissue of the hand, punctured with a 23-gauge butterfly needle, contrast was injected (less than 0.2 ml) to demonstrate nidus; then nonopacified ethanol was injected (less than 0.2 ml) (**A**). Good shunt closure was shown on repeat contrast injection after ethanol injection (**B**). **C-F**, Patient 2. Transarterial microcatheter embolization with multiple shunts in the lower leg above the ankle. For the embolization, ethanol was injected. Good shunt closure was shown on repeat contrast injection.

Embolization of Arteriovenous Malformation

No routine preprocedural workup is needed for the embolization of AVMs. However, the anesthesiologist must be aware of cardiac decompensation. The aim of endovascular treatment of AVMs is to selectively close the arteriovenous shunts. These are all complex procedures, and nontarget embolization should be avoided, because this can lead to significant tissue complications, including neurologic sequelae with paralysis.

Shunt closure can be achieved through one or more of the following techniques (see Fig. 13-32; Figs. 13-33 and 13-34):

- Direct percutaneous puncture of the AVM nidus (for nonvisceral AVMs)
- Transarterial catheter embolization using a coaxial catheter system with a microcatheter advanced as close as possible to the nidus
- Embolization of the venous outflow from the nidus,^{50,51} either by direct puncture of the vein outflow or by retrograde venous catheterization

The endovascular treatment strategy is determined by the patient's symptoms. In those patients in whom venous congestion or hemorrhage is particularly troublesome, closure from the arte-

Fig. 13-33 Onyx embolization of maxillary AVM (same patient as in Fig. 13-30, *E* and *F*). **A**, Schobinger stage III AVM supplied bilaterally by internal carotid arteries (descending ophthalmic artery branches). **B**, External carotid arteries (internal maxillary artery branches). **C**, Prompt venous drainage. **D**, Direct puncture (18-gauge needle) into the maxillary nidus. **E-G**, Subsequent Onyx injections as serial procedures over 2 years, showing progressive closure of much of the arteriovenous shunts.

Fig. 13-34 Angiographic result of AVM embolization (same patient as in Fig. 13-31). Serial embolizations with ethanol and glue were performed to control pain; both agents were injected by direct puncture and transarterial techniques at different shunt locations. Good symptom control was achieved. Completion angiogram at symptom control shows significant closure to multiple shunts in the distal forearm and hand, with preservation of digital flow. Distal ulnar artery occlusion occurred from embolizations.

rial side with an arterial catheter is preferred before closure of the venous end of the shunt. In patients with tissue necrosis, embolization from the venous end should be considered before using an arterial approach.

As AVMs invariably have many nidi, the question often asked is which nidus/nidi should be closed? With diffuse extremity disease, nidal closure at the location of symptoms such as pain would be appropriate. In patients with cardiac overload, closure of the largest shunts initially would be appropriate (Fig. 13-35).

Fig. 13-35 Recommended treatment options for extremity AVMs. **A** and **B**, Recurrent bleeding from focal thumb AVM (thumb functional)—initially embolization and if needed amputation of digit. **C** and **D**, Pain from diffuse AVM of hand (hand functional)—for embolization, no surgical option. **E**, Chronic ulceration—for amputation. **F-I**, Diffuse truncal and extremity AVM, multiple life-threatening hemorrhages—palliative embolizations performed, no surgical option.

Embolic agents used to close arteriovenous shunts include liquid embolics and coils. All agents need to be safely delivered to the target. A coaxial catheter system is essential when agents are delivered transarterially. A coaxial system uses an outer guiding catheter through which the “delivery” microcatheter for the embolics is passed. The outer catheter provides stability for the microcatheter to reach its target and also allows multiple changes of microcatheters. The commonly used liquid embolics are ethanol and the adhesive glue, N-butyl-2-cyanoacrylate (Histoacryl). The nonadhesive liquid embolic ethylene vinyl alcohol copolymer (Onyx) is favored by some interventional radiologists. Despite being the most destructive vascular endothelial agent, ethanol is not favored by some because of its associated life-threatening intraprocedural cardiopulmonary complications. However, when used appropriately, the angiographic results from the use of ethanol can be excellent. Histoacryl glue and Onyx can result in satisfactory angiographic shunt closure; however, they do not destroy the vascular endothelium, as does ethanol. Any of the three liquid agents can be injected through a microcatheter or direct percutaneous methods. Ethanol must never be injected into visceral AVMs, because the risk of parenchymal necrosis is high. Histoacryl glue is a useful alternative for visceral AVMs. In pediatrics, success has been reported for novel lifesaving neonatal liver AVM embolizations with excellent long-term outcomes.^{52,53} Traditionally, coil embolization is not recommended in AVMs; however, this technique can be useful to close the venous end of selected arteriovenous shunts, because this promotes closure of the shunts themselves.^{48,49} Flow-related aneurysms are well recognized and can be problematic and challenging to treat (Fig. 13-36).

After embolization, local swelling as expected starts immediately, and progresses over several hours, eventually subsiding by 5 to 7 days. Pain should be managed appropriately. Local tissue injury with necrosis can occur and affect skin and mucosa, with early signs evident within 24 hours; it requires careful follow-up and appropriate care in conjunction with plastic surgery. Hydration is important after the procedure to minimize the effects of hemoglobinuria, which frequently occurs with ethanol.³⁴ Oral fluids are encouraged, along with twice normal IV fluid maintenance given routinely for 4 hours after the procedure. Hemoglobinuria is managed by additional hydration with IV and oral fluids, intravenous furosemide, and occasional urine alkalinization with a sodium bicarbonate intravenous infusion.³⁴ Bed rest for approximately 6 hours is recommended when arterial catheterization is performed through the femoral artery. All relevant peripheral pulses are monitored during the first 6 hours after the procedure. All complications (see Box 13-4) require close observation and follow-up.⁴⁶⁻⁴⁹

Fig. 13-36 Flow-related aneurysms in peripheral AVMs. These occur on the arterial inflow to the arteriovenous shunts. Progressive increase in size over the years can occur. **A**, Aneurysm in patient at 12 years of age. **B**, In the same patient at 17 years of age.

AVM embolization is usually performed as an elective procedure with a 24-hour postprocedural stay. Elective intensive care admission after the procedure is needed if the AVM involves vital areas, such as the airway or oral cavity, including the tongue. At discharge, the patient should be systemically well, with no concerns regarding the treated area other than expected swelling.

Repeated embolization procedures are typically required because of the large number of shunts and a propensity for the shunts to open after treatment is started. Repeat AVM embolization is performed approximately every 8 weeks. Arrangements are made for appropriate clinical and imaging follow-up after treatment. Patients often require multiple angiographic catheterizations. The high complication risk associated with AVM embolization is the result of local and systemic problems related to the injected embolic agents, catheter technique, and devices used and risks from inadvertent embolization (see Table 13-1). Despite this, patients can often have significant improvement in their symptoms with embolization.

VASCULAR MALFORMATIONS ASSOCIATED WITH OTHER ANOMALIES

Vascular malformations (simple and/or of major named vessels) may be associated with anomalies of bone, soft tissue, or viscera. These nonvascular anomalies are often soft tissue and are sometimes associated with skeletal overgrowth or rarely undergrowth. In patients with PTEN gene-mutation–related overgrowth and vascular malformations, lifelong screening for associated malignancies is required throughout adulthood. The eponymous syndromes used for these anomalies can cause confusion, and it is always important to describe the individual vascular channel malformations and associated anomaly. In selected patients, the interventional radiologist can help with these complex disorders, but there are no cures.

Klippel-Trenaunay Syndrome

KTS is a low-flow combined vascular malformation involving abnormal capillary, lymphatic, and venous channels associated with prominent soft tissue and bony hypertrophy.^{54,55} Commonly, the malformation affects a single lower extremity. However, more than one extremity can be affected, usually asymmetrically. Macrodactyly can be seen in an uninvolved limb. The trunk (thorax, perineum, and retroperitoneum) can also be affected. The original description of KTS was a triad of physical findings: a cutaneous capillary malformation (port-wine stain), varicosities, and hypertrophy of soft tissue and bone in the affected region (Fig. 13-37). Like many vascular anomalies, the severity of the phenotype and component anomalies in KTS is variable.

Lymphatic malformations are also seen in KTS, in addition to other low-flow malformations, in the original description. This syndrome is sporadic and evident at birth. The capillary malformation component is present in the skin often as a “geographic” stain. The venous component consists of anomalous superficial embryonic veins, such as the lateral marginal vein of Servelle⁵⁶ (see Fig. 13-7). Deep venous anomalies can occur, such as hypoplasia and segmental atresias (Fig. 13-38). In lower extremity disease, venous hypertension occurs and varicosities may worsen with increasing age. The lymphatic component (lymphatic malformation) is variable and includes conducting lymphatic channel hypoplasia, lymphedema, and cystic lymphatic malformations. Microcystic lymphatic malformations are often located on the surface of the cutaneous capillary malformation and can bleed intermittently.

Extremity overgrowth is obvious at birth, and although progressive, major changes after birth are unusual. The overgrowth of an affected limb can involve the entire extremity, including the hand and foot. When a leg-length malformation affects the lower extremity, yearly monitoring is needed, because a leg-length discrepancy can occur. Radiographic monitoring of leg length

Fig. 13-37 Clinical features of KTS. Typical physical findings in three patients with lower extremity KTS with extremity overgrowth. **A**, Capillary malformation (port-wine stain), lymphatic malformation on surface of stain as small dark vesicles. **B** and **C**, Capillary malformation (port-wine stain), lymphatic malformation on surface of stain as small dark vesicles, and lateral viscosities—venous malformation.

Fig. 13-38 The deep venous system in lower extremity KTS. Venograms in two patients showing deep vein anomalies. **A**, Femoral vein hypoplasia. A venogram is performed through pedal vein injection with an ankle tourniquet to divert flow into the deep veins, also showing a multichannel embryonic lateral marginal vein. **B**, Femoral vein atresia. A venogram is performed through catheter injection into the common femoral vein with groin compression to promote retrograde filling.

is performed in those children with a leg-length discrepancy who are older than the toddler age group to assess the need for timed surgical correction with an epiphysiodesis. Infrequently, there can be undergrowth of the affected limb. The affected limb may also be enlarged in girth. However, this is the result of a combination of thickened skin, excessive fat, and an increase in abnormal vascular tissue. The muscles are usually normal in size and sometimes smaller. Vascular anomalies can be present in the muscle compartments.

Extremity pain is not uncommon and can be from various causes, such as venous hypertension and chronic venous insufficiency, cellulitis, deep venous thrombosis, thrombophlebitis, osseous venous malformations, arthropathy, neuropathy, and growing pain.⁵⁷ Thrombophlebitis of the anomalous veins occurs in up to 45% of patients, and pulmonary emboli are reported in between 4% and 25% of patients. Pulmonary hypertension has been reported in patients with KTS, possibly caused by silent recurrent pulmonary emboli.³⁴ Bleeding can be problematic from the skin and the genitourinary and gastrointestinal tracts. Patients can also have recurrent lymphatic malformation infections, cellulitis, and lymphedema.

Klippel-Trenaunay Syndrome Imaging and Treatment

Imaging plays an important role in the evaluation of KTS patients.⁵⁸ Radiographs (including CT scanography/digital radiography) are performed to measure length discrepancies in the lower extremities. MRI is the best imaging modality to study the soft tissue components of the affected area and easily demonstrates the abnormalities in the subcutaneous tissues (lymphatic malformations, venous malformations, anomalous veins, and increased fat) and muscle compartments, which may appear enlarged because of infiltration by lymphatic and venous malformations.⁵⁸ Magnetic resonance venography (MRV) can help to define the anatomy of the deep venous system and venous anomalies. The deep venous system may be hypoplastic with segmental atresias and therefore difficult to see on MRV. Further invasive assessment with conventional venography is performed when endovascular closure of venous anomalies and embryonic veins is planned. Invasive venography can be performed through a variety of techniques, including conventional

Fig. 13-39 Endovascular closure of embryonic vein in KTS. **A** and **B**, Venography shows both embryonic veins present: the lateral marginal vein (*black arrow*) draining into the common iliac vein, and the sciatic vein (*white arrow*) draining into the internal iliac vein. **C**, Endovascular closure of the lateral marginal vein performed by coil embolization of the intrafascial more deeply located in the upper end of the vein communicating with the common iliac vein and then endovenous laser ablation to the more superficial extrafascial lower end of the vein.

pedal venography, percutaneous injection of tibial veins, retrograde catheter venography, and diversion venography⁵⁹ (see Figs. 13-8 and 13-38; Fig. 13-39). Contrast venography is challenging because of the large capacity of the anomalous channels and hypoplasia of the deep veins. In the young patient, the embryonic lateral marginal vein is typically large but straight and becomes more tortuous in the older patient. This embryonic vein may be either a single channel or multiple interconnecting longitudinal channels (see Figs. 13-38 and 13-39).

For most patients, treatment is conservative.^{54,55} When lower extremities are affected, a leg length discrepancy is managed appropriately. Specific problems must be addressed when they arise, such as infections, bleeds, thromboembolic events, and extremity pain. Graded compression stockings can be extremely helpful in those patients with axial limb enlargement. Patients comment that their affected extremity can feel “lighter,” and in particular, compression garments can help with the subcutaneous venous anomalies, venous hypertension, chronic venous insufficiency, and lymphedema. A variety of topical treatments can be effective to treat skin bleeding.

Sclerotherapy can be offered to treat certain components, such as focal venous malformations, including perirectal venous malformations causing rectal bleeding, macrocytic lymphatic malformations, and bleeding cutaneous lymphatic vesicles. Recurrence after sclerotherapy, however, is recognized. Closure of the embryonic veins may offer some protection against venothromboembolic disease in KTS, and this can be achieved either through an endovascular approach using endovenous laser and coil embolization (see Fig. 13-39) or sometimes surgically (Fig. 13-40). Treatment for venous anomalies may be required when these become symptomatic, and either an endovascular or surgical approach can be performed⁶⁰⁻⁶³ (see Figs. 13-39 and 13-40). Secondary procedures are required in a significant number of patients after surgical treatments of the venous anomalies. In those patients with massive overgrowth of soft tissue, staged surgical debulking of the extrafascial compartment can be offered.⁶⁴

Prophylactic anticoagulation should be considered for KTS patients when they are undergoing long and complex interventions and surgery because of increased risk of venous thromboemboli.

Fig. 13-40 Mapping the extrafascial embryonic lateral marginal vein, its tributaries, and superficial varix for endovascular laser closure. The location of these channels, including the varix (*), are marked on the skin to access them appropriately for endovenous closure.

Parkes Weber Syndrome

Parkes Weber syndrome is a complex, combined high-flow vascular malformation with extensive capillary staining, diffuse arteriovenous shunts, and rarely lymphatic malformations. The lymphatic malformations include cutaneous vesicles, lymphedema, dilated conducting lymphatics, and chylous reflux into the limb. Macrocystic lymphatic malformations are not seen in Parkes Weber syndrome.^{58,62} The clinical findings of high flow (from the arteriovenous shunts) are characterized by localized hyperthermia, bruits, thrills, and varicosities. The condition is obvious at birth and appears as overgrowth with a “geographic” macular pink skin stain. The stain is variable in size and appearance; for example, some are faint in color. Skin, subcutaneous tissues, and muscle are affected. The extremity overgrowth is axial and longitudinal, and the disease may have a focal distribution or involves an extremity in a more diffuse/multifocal pattern (Fig. 13-41). The limb overgrowth affects soft tissue (including muscle) and bone. Arteriovenous shunting occurs through macroarteriovenous and microarteriovenous fistulas, and varicosities result from arteriovenous shunting (Figs. 13-42 and 13-43). The vascular skin stain is not a true capillary malformation as in KTS and has been described as a “pseudocapillary malformation,” because it is most likely caused by microarteriovenous fistulas, which explains the warmth when the stain is palpated, unlike the capillary malformation in KTS.

Physical findings of Parkes Weber syndrome can be confirmed easily with continuous wave Doppler examination, which shows arteriovenous shunting. Arteriovenous shunting may lead to cardiac decompensation from volume overload and can present at birth or later (see Fig. 13-43). Parkes Weber syndrome has been confused with KTS because of the extremity skin stain, varicosities, and overgrowth; in contrast, KTS has no high-flow component and does not affect extremities in a focal distribution. Macrocystic lymphatic malformations are not seen in Parkes Weber syndrome but can occur in KTS. Therefore it is easy to differentiate Parkes Weber syndrome from KTS. Although Parkes Weber syndrome can be sporadic, it belongs to the clinical spectrum of capillary malformation–arteriovenous malformation, and approximately 50% of Parkes Weber syndrome cases are associated with a *RASA1* gene mutation.⁶⁵

Fig. 13-41 Clinical features of Parkes Weber Syndrome, as shown in four patients. **A** and **B**, Patient 1. Pedal overgrowth with multifocal pink geographic macular skin stains and prominent subcutaneous veins in the distal lower extremity.

Fig. 13-41, cont'd **C**, Patient 2. Teenage girl with cardiac decompensation and a very faint macular pink skin stain and generalized overgrowth of a "warm" left upper extremity. **D**, Patient 3. Right lower extremity overgrowth (especially longitudinal) in 7-year-old girl with a warm lower extremity and multifocal dark macular skin stains. **E**, Patient 4. Generalized overgrowth of the right upper extremity in patient with diffuse "spotty" macular skin stain and a warm affected extremity.

Fig. 13-42 Parkes Weber syndrome microarteriovenous fistulas on catheter angiography. Two patients with angiographically different microarteriovenous shunts. **A** and **B**, Patient 1 (Patient 1 in Fig. 13-41) shows soft tissue staining from microarteriovenous shunts in the foot and calf, with no direct arteriovenous shunts seen. **C**, Patient 2 (Patient 4 in Fig. 13-41) shows diffuse circumferential microarteriovenous shunts with microarteriovenous fistulas seen. Both patients are unsuitable for catheter embolization, because this cannot be performed for microarteriovenous fistulas without significant complications.

Fig. 13-43 Angiography and embolization of macroarteriovenous fistulas in Parkes Weber syndrome (Patient 2 in Fig. 13-41). **A**, Patient with cardiac decompensation has multiple macroarteriovenous shunts in the upper arm fed by the circumflex humeral artery. **B**, During embolization of circumflex humeral shunts, venous outflow was controlled using an endovascular balloon in the subclavian vein. **C**, Macroarteriovenous shunts embolized successfully with glue using a coaxial microcatheter technique. **D** and **E**, Multiple macroarteriovenous shunts in the upper arm fed by the profunda brachii arteries. Staged embolization of multiple macroarteriovenous fistulas in the left upper extremity resulted in significant improvement of cardiac status.

Parkes Weber Syndrome Imaging and Treatment

MRI is recommended to evaluate the overall distribution of Parkes Weber syndrome and demonstrate the subcutaneous extrafascial anomalies, including abnormal vascular tissue, microcystic lymphatic malformations, lymphedema, and fatty overgrowth.⁵⁸ Unlike in KTS, muscle and bone hypertrophy is seen in Parkes Weber syndrome. In an affected extremity, enlarged inflow arteries and outflow veins are seen and numerous flow voids are present on spin-echo sequences. Microarteriovenous shunts can be seen as T2 signal hyperintensity in deeper tissues such as muscle.

Bony hypertrophy can result in a limb-length discrepancy, and epiphysiodesis may be required. Surgical debulking is not generally performed, because overgrowth affects muscle and bone.

Catheter angiography can demonstrate microarteriovenous and macroarteriovenous shunts (see Figs. 13-42 and 13-43). Catheter angiography is not usually performed unless the patient has local pain, tissue ulceration, or cardiac decompensation. The catheter angiogram can identify macroarteriovenous fistulas, which may be suitable for endovascular closure, resulting in symptom improvement. Diffuse microarteriovenous shunts can be seen in the subcutaneous fat and

muscle and are unsuitable for catheter embolization. The AVFs may occur throughout an entire extremity or more focally. Endovascular closure of macroarteriovenous fistulas reduces shunting, leading to improved tissue perfusion with reduced pain, healing of skin ulceration, and control of cardiac overload (see Fig. 13-43).

Both KTS and Parkes Weber syndrome are complex vascular malformations, and although there are no cures, the interventional radiologist can provide useful therapeutic options with symptom improvement.

KEY POINTS

- Patients with vascular anomalies will benefit from a multidisciplinary team approach to patient care.
- Two features that help differentiate vascular tumors from vascular malformations are (1) the patient's age when the lesion was first noticed and (2) the growth of the lesion over time and if the growth is commensurate with that of the child.
- The postnatal diagnosis of a vascular anomaly can be made in most patients based on history and physical examination.
- The antenatal diagnosis of vascular anomalies relies on imaging with fetal ultrasonography and MRI.
- Vascular malformations progress throughout childhood and persist throughout adulthood. Low-flow malformations can be differentiated from high-flow malformations on physical examination.
- The two most helpful imaging modalities used to establish or confirm a diagnosis and define disease extent are ultrasonography and MRI.
- Imaging plays a significant role in the diagnosis of vascular anomalies when lesions are deep with no visible cutaneous signs.
- Basic MRI with T1, T2, and postcontrast sequences (sometimes with fat saturation) is highly tissue specific when imaging vascular anomalies. MRA sequences are not required to establish a diagnosis.
- "Bedside ultrasound" is extremely useful in a clinic setting to provide and/or confirm a diagnosis in selected patients. A high level of skill is required to perform and interpret the ultrasonography.
- Most vascular anomalies are not life-threatening; however, some can threaten life because of associated severe coagulopathies and hemorrhage, cardiac failure, venothromboembolic events (including pulmonary embolism), sepsis, pressure effects on vital structures, associated malignancies, and iatrogenic insults/inappropriate therapies.

Continued

KEY POINTS (continued)

- Not all vascular anomalies require treatment. The need for treatment is often determined by the lesion and its associated effects.
- Medical therapies are often used for vascular tumors and radiologic/surgical therapies for vascular malformations. Multimodal therapies may be required in some cases.
- Infantile hemangioma is the most common tumor of infancy and along with all vascular tumors should be managed by a pediatric dermatologist.
- Most babies with infantile hemangiomas do not require imaging.
- Capillary malformation (port-wine stain) is the most common vascular malformation. Treatment, if required, is performed with pulsed dye laser.
- Cystic lymphatic malformations can be differentiated from common venous malformations, because they are not fully compressible, show no refilling on dependency/increased venous pressure, and do not have phleboliths.
- It is important to image a cystic lymphatic malformation before treatment to assess the amount of macrocystic and microcystic components within the lymphatic malformation. This aids in appropriate treatment planning.
- Sudden expansion is unique to cystic lymphatic malformations and occurs as a result of self-limiting intralesional hemorrhage or infection.
- In patients with venous malformations, high D-dimer and low fibrinogen levels indicate a localized intralesional coagulopathy within the venous malformation. D-dimer elevation in this setting does not indicate a deep venous thrombosis in most patients.
- The coagulopathic risk in low-flow malformations occurs in two main groups of patients: those with diffuse venous malformations in which there is a localized intralesional coagulopathy, and those with embryonic veins, typically in KTS and CLOVES syndrome.
- Radiologic treatments are an important first-line therapy for many patients with cystic lymphatic malformations, common venous malformations, and AVMs. Many patients can be helped with sclerotherapy, embolization, and laser techniques.
- AVMs are some of the most challenging vascular malformations, with lesions controlled rather than cured by present-day therapeutic approaches. High recurrence rates are seen in most patients treated for extracranial AVMs.

- KTS is a combined low-flow malformation with overgrowth. The management of KTS is mainly conservative. Prophylaxis against venothromboembolic events, during high-risk interventions and avoidance of other thrombotic risk factors (including the use of the oral contraceptive pill), must be considered.
- Parkes Weber syndrome is a combined high-flow malformation with overgrowth. If required, endovascular catheter closure (embolization) can be performed if the arteriovenous shunts are large enough. The microarteriovenous fistulas commonly seen cannot be treated by embolization.

2. Wassef M, Blei F, Adams D, et al; ISSVA Board and Scientific Committee. Vascular anomalies classification: recommendations from the International Society for the Study of Vascular Anomalies. *Pediatrics* 136:e203, 2015.
This is the updated official ISSVA classification of vascular anomalies. Vascular tumors now include benign, locally aggressive/borderline, and malignant categories. Vascular malformations now include “simple,” “combined,” and named vessel categories and also malformations associated with other anomalies. A category for provisionally unclassified vascular anomalies is new, thus providing a category for lesions of an uncertain nature (tumor versus malformation).

Conjoined Twins

Richard J. Redett • Ronald M. Zuker

HISTORY

Conjoined twins have fascinated the medical profession and general public since antiquity. Early Greek and Roman scholars theorized that maternal impressions or mortal imperfection and parental sin were to blame for the birth of conjoined twins.¹⁻³ Reflecting the social prejudices of the era, conjoined twins were often referred to as monsters. These children were felt to be warnings from God to the parents to amend their life against immorality.¹ Conjoined twins who survived were religious and societal outcasts and were often forbidden burial in consecrated ground.

In his textbook, *De Generatione Animalium* (*On the Generation of Animals*), Aristotle attributed conjoined twins to the quantity of semen and the shape of the womb. Wombs that were too small constrained the seed of twins, causing them to become congested and joined. His theories of embryogenesis prevailed well into the thirteenth century.

Sixteenth-century surgeon Ambroise Paré⁴ reported that Hippocrates believed “too great a quantity of seed” was responsible for multiple births and conjoined twinning. In contrast, “a seed that is lacking in quantity” was thought to lead to limb agenesis and missing body parts. In his treatise, *On Monsters and Marvels*, Paré⁴ described several cases of imaginary and real parapagus, craniopagus, ischiopagus, and parasitic conjoined twins. He also provided illustrations from twin specimens he reportedly had in his possession.

The Biddenden Maids, Mary and Eliza Chulkhurst, are probably the first documented case of conjoined twins.⁵ Born in the village of Biddenden, Kent, England in 1100, they spent their lives joined as pygopagus twins. Early illustrations depicted the sisters united at the hips and shoulder (Fig. 14-1, *A*), although they were instead probably joined only at the buttocks. They lived a prosperous existence and at their death, bequeathed a modest plot of land to the village parish.

Fig. 14-1 A, Pygopagus twins—the Biddenden Maids. B, Biddenden Maid cakes were distributed annually to the poor in memory of the sisters.

Interest on the annual rental of the land was used to distribute cakes bearing the sisters' image to the poor on Easter Sunday (Fig. 14-1, B). After the death of one twin at age 34, the other sister refused to be separated, stating, "As we came together, we will go together." The second sister died 6 hours later.

Dicephalus (now called *parapagus*) conjoined twins have attracted much attention. Historical illustrations depict these individuals as sharing a single body with two separate heads. The earliest authenticated case is of two Scottish brothers born in 1490.⁶ With the help of King James IV of Scotland, these children became talented musicians and linguists. They lived to the age of 28.

The most well-known parapagus twins were the brothers Giovanni and Giacomo Tocci, born in northern Italy in 1877⁶ (Fig. 14-2). Their social and medical history is well documented, providing much insight into their lives.^{6,7} When the children were 1 month old, they were put on exhibit at the Turin Academy of Medicine for examination by physicians and the public.⁷ They shared a pair of normal legs and were joined to the level of the sixth rib. Each twin had independent control of one leg, making coordinated walking difficult. This separate control of each limb has interesting implications, as will be discussed later in this chapter. As with most "double monsters," they unwillingly led their life touring the world, being promoted with broadsides and pamphlets as the "Two-Headed Boy," and the "Greatest Human Phenomenon Ever Seen Alive." Tired of the degrading nature of living as a sideshow attraction, the twins retired into secrecy at the age of 20.

The original Siamese twins, Cheng and Eng Bunker, were medical and public wonders of the nineteenth century (Fig. 14-3). Connected by a thin abdominal band (omphalopagus), they came to public attention as a display in P.T. Barnum's circus. They married different women (who were sisters), fathered 21 children, and went on to become successful businessmen and farmers. They frequently argued and appealed to their physician for separation. Their request was always denied, citing sure death if surgery were ever undertaken. Autopsy after their death demonstrated a small "tract of portal continuity" consisting primarily of skin, hepatic, and vascular tissue that would have made separation relatively easy today—and then.⁸

Fig. 14-2 Parapagus twins—the Tocci brothers from Northern Italy.

Fig. 14-3 The original Siamese twins, Cheng and Eng Bunker.

CAUSES

Until recently, incomplete fission of a fertilized ovum was the accepted hypothesis for the cause of conjoined twins.⁹⁻¹¹ New insight into embryogenesis has provided evidence that conjoined twins “result from the secondary union of two originally separate monovular embryonic discs.”¹² All conjoined twins are monovular and monoamniotic and therefore identical from both phenotypic and immunologic perspectives.^{12,13}

Studying more than 1200 cases of conjoined twins, Spencer¹² cited this process of “fusion” as the most plausible theory for conjoined twinning. During the third or fourth week of development, the previously separate embryonic discs reunite either dorsally (craniopagus, rachipagus, pygopagus) or ventrally (cephalopagus, thoracopagus, omphalopagus, ischiopagus, parapagus) at sites where surface ectoderm is absent or eventually fuses or opens.¹² These areas include the anlage of the heart (thoracopagus) and diaphragm (omphalopagus), the oropharyngeal (cephalopagus) and cloacal membranes (ischiopagus and parapagus), the neural tube (craniopagus, rachipagus,

Fig. 14-4 Union of two embryonic discs. **A**, Development of normal individual trilaminar embryo at 3 to 4 weeks. **B**, Embryonic discs reuniting at open areas with subsequent ventral conjoined unions. **C**, Embryonic discs reuniting at open areas with subsequent dorsal conjoined unions.

and pygopagus), and the periphery of the embryonic discs.¹² The union is always homologous (for example, head to head or tail to tail) and can be oriented from rostral to caudal, depending on the relative temporal-spatial relationship of the embryonic discs at the time of fusion (Fig. 14-4).

EPIDEMIOLOGY

According to The International Clearinghouse for Birth Defects Monitoring Systems and the Birth Defects Monitoring Program (BDMP),^{14,15} the estimated mean rate of conjoined twinning is 1 to 1.3/100,000 births, with a significant difference between nonwhites (1.59/100,000) and whites (0.923/100,000), although monozygotic twinning appears to be constant among various ethnic groups. Less than 1% of all monozygotic twins are conjoined.¹⁶ There appears to be no effect of maternal age or parity on conjoined twinning^{15,17}; 40% to 50% of conjoined twins are spontaneously aborted.^{14,15} The majority of conjoined twins are female, with a female/male ratio of 3:1.^{14,15,18,19} Although older data suggest most conjoined twins are born in the spring, more recent studies demonstrate no seasonal trends.^{15,18}

Källén¹⁹ conducted an epidemiologic study of conjoined twins and reported the following information: twins joined in the midportion of the body (thoracopagus, omphalopagus, rachipagus, parapagus) are the most common, with thoracopagus twins representing the majority (30% of all conjoined twins); only 12% of conjoined twins are joined cephalad (craniopagus, cephalopagus); caudal junction (ischiopagus, pygopagus) accounts for 25% of conjoined twins; parasitic twins represent 6%; and malformations include facial clefts, anencephaly, spina bifida, esophageal or gut atresia, gastroschisis, omphalocele, and limb reduction. Data on drug exposures early in pregnancy indicate that thyroid supplementation and the use of prochlorperazine and infertility medications such as clomiphene may be associated with conjoined twinning.^{14,19-21} A recent study by Steinman¹⁶ reported an increased risk of conjoined twinning following the use of oral contraceptives.

NOMENCLATURE

Several classification systems describe the various patterns of conjoined twins. All incorporate the most prominent site of union, followed by the Greek suffix *-pagus*, meaning “joined.” We recognize eight types of conjoined twins, as described by Spencer¹² (Box 14-1 and Fig. 14-5).

Box 14-1 Types of Conjoined Twins

Ventral

Rostral

1. Omphalopagus (umbilicus)
2. Thoracopagus (chest)
3. Cephalopagus (head)

Caudal

4. Ischiopagus (hip)

Lateral

5. Parapagus (side)

Dorsal

6. Craniopagus (helmet)
7. Rachipagus (spine)
8. Pygopagus (rump)

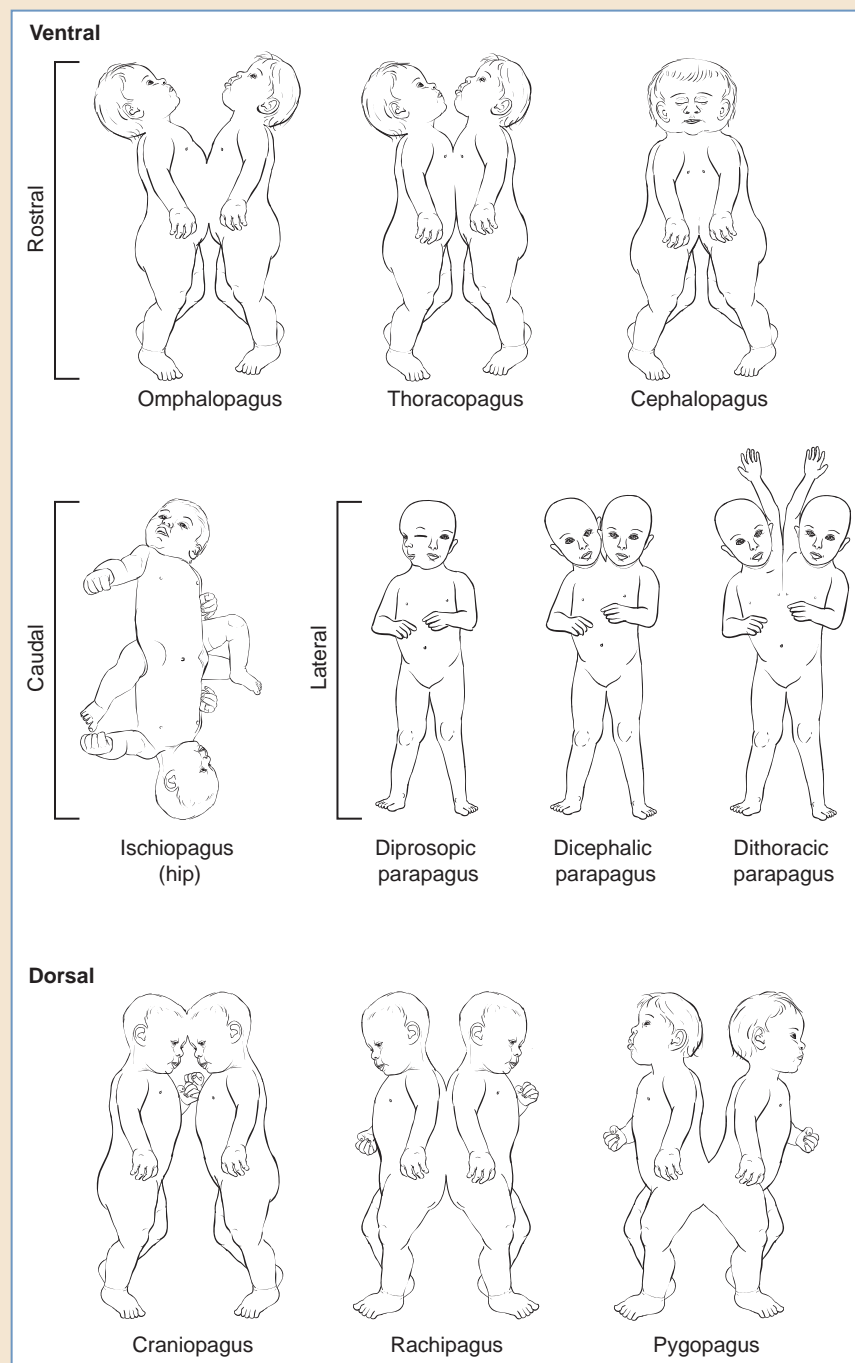

Fig. 14-5 Classification of conjoined twins.

In addition, the prefixes *di-*, *tri-*, and *tetra-* are used to describe the number of shared anatomic structures when they precede *-prospus* (face), *-brachius* (upper extremity), and *-pus* (lower extremity). We find this classification system unambiguous and concise, thus permitting the accurate exchange of important anatomic information when discussing the surgical management of conjoined twins.

Craniopagus

Craniopagus twins represent 2% to 6% of conjoined twin deliveries^{11,22} (Fig. 14-6). Approximately one set of craniopagus twins is born per 2 million live births.²² As with all conjoined twins, craniopagus twins are predominantly female (80%).²² Other intracranial and extracranial abnormalities are common in craniopagus twins.²³

The embryologic fusion of craniopagus twins involves the skull and primitive neural folds.²⁴ Craniopagus twins likely form after the fourth week of development by fusion of two separate embryonic discs at the cranial end of the open neuropore.²³ They can share scalp, calvarium, dural sinuses, and surfaces of the brain; however, the face, foramen magnum, and spine remain separate.²⁵ Varying degrees of interaxis and rotational alignment at the site of union can produce a wide range of anatomic orientations. Facial and skull asymmetry can be present.²³ The exact site of junction and the tissue layers involved also vary. Winston²² reviewed all 79 reported craniopagus twins from 1496 to 1987 and proposed a classification system based on the embryologic origin of the shared tissue (deepest shared structure) (Box 14-2). Craniopagus twins sharing

Fig. 14-6 Craniopagus twins.

Box 14-2 Winston Classification of Craniopagus Twins

- Type A: Junctions of scalp, subcutaneous tissue, and possibly bone (least common)
- Type B: Junctions of dura mater (least common)
- Type C: Junctions of leptomeninges (most common)
- Type D: Junctions of contiguous central nervous system (brain)

scalp, subcutaneous tissue, and possibly bone are referred to as having type A junctions. Those who share dura mater are type B. Types A and B are the least common types. Type C craniopagus twins share leptomeninges and are the most common type.²² Type D craniopagus twins have a contiguous central nervous system (that is, brain). Type D junctions occur in 10% to 15% of craniopagus twins.

Craniopagus twins who have contiguous cerebral cortices demonstrate completely independent behavior.²⁶⁻²⁸ Electroencephalographic evidence confirms independent electrical activity, suggesting there are no shared neuronal pathways, even in twins who have continuous central nervous systems.^{22,29,30}

It is important to determine the status of the dural sinuses before attempting surgical separation. A shared dural sinus can be difficult to reconstruct and can greatly affect morbidity and mortality. Blood loss can be massive, resulting in significant neurologic impairment. Attempts at dural sinus reconstruction using cardiopulmonary bypass and hypothermic circulatory arrest have been largely unsuccessful.³¹

The first successful separation of craniopagus twins in which at least one child survived was performed in 1953 by Dr. Herbert Grossman.²⁷ Preoperative studies consisted of electroencephalography, pneumoencephalography, and carotid angiography. Because tissue expanders were not yet developed, long, narrow scalp flaps were “delayed” over a 6-month period to improve their vascularity and venous drainage before rotation. The first attempt at surgical separation occurred when the twins were 14 months old but was aborted intraoperatively because of high blood loss and technical difficulties. The final separation was completed a month later, and the wounds were closed with the previously delayed skin flaps and split-thickness skin grafts. Both children survived the operation, but one died a month later as a result of irreversible neurologic injury and overwhelming infection.

Hoyle³² reported 26 cases of attempted surgical separation of craniopagus twins. The majority of these involved no cerebral connection. The perioperative mortality rate for cases with conjoined cerebri was 61%. Approximately 50% of the twins with no cerebral connection survived separation. Emergent separation was associated with nearly 80% mortality.

Spencer²³ studied 30 attempts to separate craniopagus twins. The majority of these children had large parietal unions with shared venous sinuses. Postoperative complications included neurologic deficits, subdural fluid collections, and hydrocephaly. Half of the twins died, and 17 had neurologic impairment. Only seven children were normal at the time of follow-up.

Cephalopagus

Sometimes confused with craniopagus twins, cephalopagus twins are instead conjoined ventrally in the cephalic portion of the body as a result of a union of the oropharyngeal membrane^{23,25} (Fig. 14-7). The union extends from the head to the umbilicus and includes the brain, foregut, heart, diaphragm, and liver.²⁵ Cephalopagus twins have two faces on opposite sides of the head. One face may be incomplete. A rare form of conjoined twins, cephalopagus twins occur at a frequency of 1 in 3 million births.³³

Omphalopagus and Thoracopagus

Omphalopagus (Fig. 14-8) and thoracopagus (Fig. 14-9) twins can be differentiated by the status of the heart. Both are joined ventrally from the thorax to the umbilicus, but thoracopagus twins always share a heart. Each twin has two arms and two legs and a separate pelvis. Omphalopagus and thoracopagus twins have varying degrees of liver and upper gastrointestinal tract fusion.

In most cases of thoracopagus twins, separation is declined because of the shared heart. In situations in which emergency separation is attempted, the death of at least one twin usually ensues.³⁴⁻³⁶ Elective separation can be performed if the cardiac defect can be reconstructed to allow survival of one twin.

Fig. 14-7 Cephalopagus twins.

Fig. 14-8 Omphalopagus twins with independent hearts.

Fig. 14-9 Thoracopagus twins with a shared heart.

Many of the reported naturally occurring deaths of thoracopagus twins happen very shortly after birth.³⁶ Recent reports describe the successful use of a procedure called *ex utero intrapartum treatment* (EXIT) to ensure adequate uteroplacental gas exchange and hemodynamic stability in a pair of thoracopagus twins during the birth process.^{34,37} In this procedure, the twins are delivered through cesarean section, and the airway is established before clamping the umbilical cord. These results are encouraging and may provide a means of improving perinatal survival in cases of shared cardiac structures in which separation is considered appropriate.

Parapagus

Previously called dicephalus, parapagus twins are united laterally and share a common pelvis (Fig. 14-10). They represent 11% of all conjoined twins.⁶ Their union can extend cephalad and can include the entire abdomen (dithoracic parapagus), the thorax with two separate heads (dicephalic parapagus) (Fig. 14-11), or the head with two separate faces on the same side of the head (diprosopic parapagus).³⁸ Many dicephalic parapagus twins have conjoined hearts, making surgical separation or long-term survival difficult.³⁹ Shared spinal cord innervation will result in significant neurologic deficits if separation is undertaken.³⁴ Many of these twins are offered only supportive care and die shortly after birth.^{34,39}

Fig. 14-10 Parapagus (dicephalus) twins.

Fig. 14-11 Dicephalic parapagus twins.

Ischiopagus

Ischiopagus twins present true multidisciplinary challenges when planning separation (Fig. 14-12). United ventrally, they frequently share a liver, gastrointestinal tract, genitourinary system, and pelvic bones, requiring the participation of general surgeons, urologists, and orthopedic and plastic surgeons. The surgeries tend to be lengthy and demand an experienced team of anesthesiologists, surgeons, and nurses. Ischiopagus tripus (three legs) conjoined twins each have a normal leg and a shared malformed third leg, frequently with dual vascular and nerve supply. The soft tissue of the third leg is usually used to cover the soft tissue defect of one of the twins, leaving each twin with one viable leg. Zuker et al⁴⁰ successfully transplanted the entire hindquarter of one dying ischiopagus twin to her sister, thereby leaving her with two “normal” legs. This was the first reported successful lower extremity transplant.

Pygopagus

According to the fusion theory of embryogenesis, pygopagus twins form from the union of two separate embryonic discs in the caudal portion of the open neuropore and can therefore share a buttock, sacrum and coccyx, distal gastrointestinal tract (one anus, two rectums), and part of the genitourinary system^{23,41} (Fig. 14-13). Separation frequently requires preoperative tissue expansion with the subsequent expander capsule being used to reinforce the dural closure if there is a shared spinal cord.⁴¹ Pygopagus twins represent 18% of all conjoined twins.⁴¹

Fig. 14-12 Ischiopagus twins.

Fig. 14-13 Pygopagus twins.

Fig. 14-14 Rachipagus twins.

Rachipagus

This rare type of conjoined twin is united dorsally (Fig. 14-14). In an extensive review of 1200 conjoined twins, Spencer⁴² identified only one typical case and 20 dorsal parasitic twins that were reclassified as rachipagus twins. The one typical intact rachipagus twin case was joined from the occiput to the sacrum, but the bony union consisted only of the thoracolumbar vertebrae.²⁵

ETHICAL CONSIDERATIONS

Moral, ethical, legal, and religious issues frequently complicate the separation of conjoined twins. The parents' and patients' right to privacy, presumed surgical consent, the allocation of organs and genitalia, and the potential sacrifice of one twin for the benefit of the other make the decision to separate some twins difficult. In addition, quality of life and functional outcome with and without separation are important considerations. We have found that including a medical ethicist in the team can be helpful when making such challenging decisions with the family. The separation of conjoined twins almost always attracts a circuslike media atmosphere. Every attempt should be made to respect the parents' and patients' right to privacy.

Several religious and legal considerations are worthy of review. A recent British High Court decision allowed the separation of conjoined twins against the parents' wishes when it was deemed necessary to save the life of one child. The ischiopagus twins involved were Jodie and Mary, born in England in August 2000. Mary had a hypoplastic, poorly functioning heart and was dependent on Jodie for perfusion. The parents were of a strong religious background and "could not begin to accept or contemplate that one of their children should die for the other to survive."⁴³ The English Court of Appeal granted proxy consent to the hospital, and surgery was performed. The weaker twin, Mary, died within 20 hours of the start of surgery. Although "reasonable attempts to separate conjoined twins are supported by both law and ethics,"⁴⁴ every effort should be made to make the decision whether to separate the twins through discussion with the parents.

SURGICAL SEPARATION

Our technical expertise and understanding of conjoined twin physiology continue to improve, and the separation of conjoined twins is no longer experimental. Large medical centers have gath-

ered enough experience that a properly planned and executed operation can usually end with the expected results. Although the decision to separate twins when both are intended to survive is seemingly “easy,” very few if any long-term studies evaluating functional outcome after surgery are available. Many of these children are left with significant neurologic deficits (especially craniopagus twins) and functional limitations as a result of lower extremity deficiencies.

Approximately 50% of conjoined twins die within the first day after birth.³⁴ Twins who require emergent separation have survival rates of 30% to 50%, and those who go on to elective operation have a survival rate of 80% to 90%.^{36,37,45} In a series by O’Neill et al,³⁵ nearly 40% of twins who survived separation died within 10 years from other serious associated congenital anomalies.

Historically, the separation of conjoined twins was thought to be “above human skill.” German cartographer Sebastian Munster⁴ described a set of craniopagus twins separated after the death of one twin at 10 years of age in 1495. The remaining twin died shortly thereafter from the wound she sustained during the separation.

The first attempt at separation of living conjoined twins is said to have occurred in 1689, but documentation of the event is scant.^{32,46} The procedure reportedly involved applying a constricting ligature across a thin band of tissue that connected omphalopagus twins.³² It is believed that the first confirmed successful separation was undertaken in 1902 with 12-year-old omphalopagus twins who shared a small hepatic bridge.⁴⁶ Their separation was prompted by the development of tuberculous peritonitis in one of the twins. Both children survived the operation, but the twin with peritonitis later died of her disease.

Surgical outcome after separation of conjoined twins has improved since the first modern-day separations were attempted in the 1950s.³² Absolute success rates are difficult to determine, because one twin is sometimes allowed to die during surgery. The separation of conjoined twins where both are intended to survive is most successfully performed in ischiopagus twins and least successfully in thoracopagus twins.³²

Emergent separation of conjoined twins carries a higher mortality rate than elective separation preceded by planning and coordination. Preoperative planning and coordination of various surgical teams are central to a successful separation. In this way the extent of various defects can be more adequately appreciated. Stage-setting procedures can be incorporated into the overall treatment plan. To provide additional tissue for coverage, tissue expansion may be used. Intraperitoneal tissue expansion has been described by Zuker et al⁴⁷ to provide not only adequate surface coverage but also adequate abdominal and pelvic support.

IMAGING

Prenatal

Prenatal diagnosis and detailed evaluation helps to prepare the parents and treating team for the birth of conjoined twins. By accurately defining the anatomy and associated malformations, important decisions can be made regarding counseling the parents and planning for the delivery and postnatal course. Useful imaging tools include ultrasonography, echocardiography, CT scanning, and ultrafast fetal MRI.³⁴

Prenatal diagnosis of conjoined twins can be made using ultrasonography during the first trimester. Several sonographic findings are used to aid in the diagnosis of conjoined twins.^{17,48} Ultrasound findings suggestive of conjoined twins include the lack of a separating membrane between the twins, more than three vessels in the umbilical cord, and the inability to separate the fetal bodies.^{17,48} A formal prenatal evaluation using ultrasonography, MRI, and echocardiography should be performed after 18 weeks’ gestation to further define the anatomy and presence of other congenital anomalies.³⁴ Serial sonographic imaging is performed throughout the pregnancy.

Postnatal

CT with three-dimensional bony reconstruction is helpful postnatally for planning surgical separation. CT also provides useful information regarding the complex anatomic relationship of shared organs. The less invasive MRI is preferred to angiography when delineation of the vascular system is needed. As our personal experience increases, we are less dependent on barium studies of the gastrointestinal tract to determine the configuration of the small and large intestine. We and others have noted common and predictable gastrointestinal patterns associated with different types of conjoined twins.⁴⁹

Pregnancy

After a diagnosis of conjoined twins is made, the parents are often counseled regarding the option of terminating the pregnancy. Near-term cesarean section, performed in a tertiary care facility, is recommended for the delivery of conjoined twins.¹⁷ A prepared neonatal ICU with pediatric anesthesia and surgery support is required. Accurate prenatal diagnostic investigations will help determine the need for emergent surgical separation after birth.

PREOPERATIVE PLANNING

The planning process for separation of conjoined twins may be relatively simple or extremely complex. Examples of each will be illustrated in the following cases. Before the surgical separation, a multitude of issues must be resolved. The children must be in optimal condition from a nutritional and developmental standpoint. All ethical decisions regarding separation and the potential for complications must be disclosed to the family. It can be helpful to involve psychologists, social workers, and ethicists in difficult cases in which one of the children may die or be significantly impaired after separation.

Surgical planning should include the various surgical subspecialties, anesthesia, nursing, and the ICU. We include the facility engineers to ensure an adequate power supply, outlets, and overhead lights for two or more teams. We have found that a series of multidisciplinary meetings and an open discussion of each subspecialty's concerns is extremely helpful in anticipating and jointly solving the many concerns that may arise. With complex surgical separations it is also helpful to

Fig. 14-15 Specially designed operating room table for separating craniopagus twins.

have a “run-through.” This is performed in the operating room where positioning of the children and movement of the operating tables can be appropriately planned. We have used a specially designed operating room table when separating craniopagus twins (Fig. 14-15). An electrocautery pad should be placed on either twin at the beginning of surgery to ensure adequate grounding once they are separated.

Anesthesia

Two teams of anesthesiologists are required for any surgical separation. They must be given time and space to provide an adequate environment for the surgery. Major issues such as central lines, intubation, assessment of the common circulation, and provision of adequate volume replacement must be addressed. Anticipation of the logistics of the separation is also essential so that lines do not get entangled or twisted at the time of movement of one child to another site. This is when a run-through is often helpful in anticipating such problems.

The Role of the Plastic and Reconstructive Surgeon

The plastic and reconstructive surgeon will help plan the surgical approach to separation and provide reconstruction of soft tissue defects. This may be relatively simple as with the lesser degrees of omphalopagus twins, or it may be extremely complex as with ischiopagus twins. Soft tissue replacement may involve skin only but also often involves support structures for the abdominal wall, pelvic floor, and even the cranium. In complicated cases it is very helpful to have models to help in the planning process (Fig. 14-16). To provide adequate soft tissue, expansion techniques may be needed. The use of older concepts such as pneumoperitoneum have been replaced with the use of tissue expansion.

As with other planning procedures, planning in reverse is essential—anticipating the potential for problems. Minor wound breakdown should be anticipated and backup plans for coverage prepared. As with other wound-healing problems, provision of adequate nutrition, adequate antimicrobial coverage, and patience to allow for secondary healing will provide the foundations for success.

Fig. 14-16 Models can be very helpful in planning the separation of conjoined twins. **A**, Ischiopagus clay model. **B**, Craniopagus twin models before and after tissue expansion.

CASE EXAMPLES

The following case examples illustrate the principles of surgical separation of conjoined twins. Each of these relatively rare procedures must be assessed and planned independently.

Craniopagus Twins

An ultrasonographic examination during late pregnancy showed conjoined craniopagus twins and a third independent fetus. The three babies were delivered successfully through cesarean section in Karachi, Pakistan. The third baby was unaffected. Separation of the conjoined babies was requested, and the infants were transferred to Toronto under the care of a senior neurosurgeon at our hospital. The site of union was at the vertex of each skull with a slight 30-degree rotation (Fig. 14-17, *A*). There was a shared segment of cerebral cortex and a shared sagittal sinus. The cardiac status of one baby was excellent, whereas it was quite poor in the second. This became very important regarding the timing of separation surgery. The gastrointestinal systems were normal in each child. One baby had two normal kidneys, whereas in the other baby one kidney was absent and the other kidney was severely hydronephrotic and nonfunctional, indicating the entire renal filtration mechanism was limited to the baby with two normal kidneys. Separation would leave the other baby with no renal function.

After considerable discussion involving religious leaders, ethicists, and psychologists, it was decided to transplant one kidney from the healthy baby to the second. This became a significant ethical problem in that, by Ontario law, transplantation from a live donor is not allowed until the age of 18. However, the conjoined twins were legally considered one entity, and thus transplantation from one part of the single entity to another would be allowed. The kidney transplantation was performed successfully 6 months before the separation.

Cerebral circulation was investigated, and attempts were made to partially close the shared venous drainage systems so that each baby would have appropriate independent venous drainage. This was undertaken through embolization techniques, which had not been done previously.⁵⁰ The conjoined cranial surface was broad, indicating a significant need for scalp and calvarial reconstruction. Most of the bony structures could be reconstructed with split calvarial bone grafts, but we would need additional tissue expansion to provide sufficient scalp coverage. Two tissue expanders were placed on either side of the conjoined cranium (Fig. 14-17, *B*).

The second twin's cardiac status deteriorated, necessitating urgent separation before tissue expansion was complete. After the scalp flaps were elevated, a strip of conjoined cranium was removed circumferentially. This provided access to the brain for the neurosurgeons and was used in the calvarial reconstruction. Despite prior embolization efforts, the separation was difficult and blood loss was high. The cerebral structures were separated and the large dural defects reconstructed with dural grafts. The split calvarial grafts were used for skull reconstruction. The scalp flaps were repositioned and full coverage was achieved (Fig. 14-17, *C*). The babies were transferred to the PICU and extubated 48 hours after surgery. There were some areas of scalp wound breakdown that necessitated wound care and eventual skin grafting. One child never fully regained consciousness and died 2 weeks after surgery. The cranium of the surviving twin coalesced nicely, and the scalp flaps survived and produced luxuriant hair growth. There were some areas of alopecia at the site of the skin grafts and at the sites of scalp flap union. Over the course of the next month, the baby was eating normally and functioning at the appropriate developmental level (Fig. 14-17, *D*). She returned to her native Pakistan with her parents and the other unaffected triplet.

Fig. 14-17 A, Craniopagus twins. B, Tissue expanders were placed and inflated before separation. The tissue expansion process could not be continued to its planned length, because one twin's cardiac status deteriorated, necessitating urgent separation. C, After separation, with skull and scalp reconstruction. D, The surviving twin after recovery from the separation surgery.

Female Omphalopagus Twins

A Canadian family living in Mexico was found to be expecting conjoined twins during routine ultrasonographic examination. The mother was transferred to our hospital, where the children were delivered at 38 weeks' gestation through cesarean section. Both girls were healthy and classified as omphalopagus twins (Fig. 14-18, A). Ultrasound evaluation identified a 6 cm conjoined union consisting of a segment of shared liver. Evaluation of the biliary systems found normal biliary tracts going from each baby's main liver to the same baby's small bowel. Separation was deemed to be fairly simple, consisting of skin and abdominal wall coverage and division of the shared liver. It should be noted that on occasion the biliary systems can be crossed. In such cases, repositioning the biliary drainage system is necessary for adequate hepatic function.

A team of general surgeons, plastic surgeons, anesthesiologists, intensivists, and nurses was assembled. The general surgeons led the team, because they were responsible for separating the liver. The liver was separated, and confirmation of biliary drainage for each baby was ensured. On separation one baby was placed on a second operating table for reconstruction of the abdominal walls. The abdominal walls were closed primarily in layers without difficulty. Umbilical

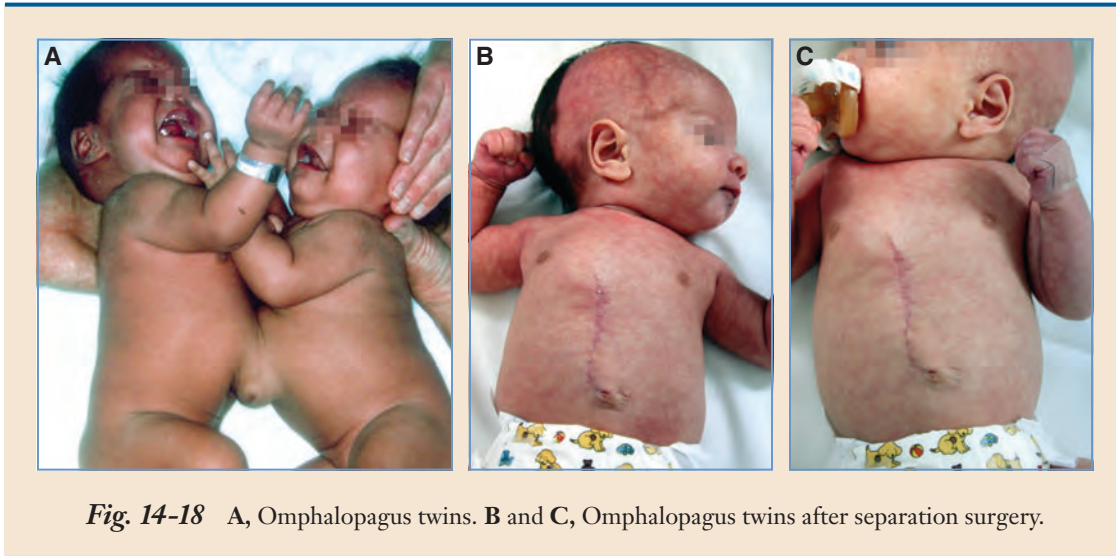

Fig. 14-18 A, Omphalopagus twins. B and C, Omphalopagus twins after separation surgery.

reconstruction was also performed (Fig. 14-18, B and C). The children were transferred to the PICU, extubated on day 1, and transferred to the pediatric surgery ward on day 3. They remained in the hospital for an additional 10 days to ensure adequate gastrointestinal function and appropriate wound healing. The children were discharged home and have developed normally, with no significant abdominal wall deformity.

Male Omphalopagus Twins

A woman in rural Zimbabwe was found to be carrying omphalopagus conjoined twins on routine ultrasound examination. The babies were delivered without complication at 37 weeks' gestation and found to be healthy. They had a large area of union from the xiphoid process to just below the umbilicus. They were also noted to have unilateral complete cleft lip and palate. After nutritional stabilization they were transferred to our hospital (Fig. 14-19, A).

Detailed investigations demonstrated a shared liver with separate biliary systems, intestinal tracts, and genitourinary systems. Despite a significant chest wall deformity, the hearts were separate.

Because of the family's socioeconomic needs, a variety of volunteer organizations helped with the transportation, housing, and hospital costs. All medical fees were waived. The children underwent nasogastric feeding to improve their nutritional status for 3 months before separation. Plans for separation were made, and a variety of team meetings were held.

As in the case shown in Fig. 14-17, the liver would be separated and confirmation of appropriate biliary drainage would be ensured. The children's union was very broad, involving the lower chest wall and abdomen. At 5 months of age, a large tissue expander was inserted over the conjoined section of the thoracic cavity. The expansion progressed satisfactorily until week 10, when the expander became infected and eroded through the skin. The expander was unsalvageable and was removed. Because all of our expansion was lost, we would need to use artificial fascia for the fascial defects and regional skin flaps for the skin defect. With the help of three-dimensional imaging, our surgical plan included an incision that was somewhat offset to provide for direct soft tissue coverage for one baby. For the second baby we would require a regional flap to cover the essential areas of the lower chest and upper abdomen.

Fig. 14-19 A, Omphalopagus twins. B, Closure of twin A. C, Closure of twin B. D, The boys after recovery from separation surgery.

Surgical induction was undertaken without incident, and our surgical incisions were outlined. It is helpful to staple along the planned incision lines, particularly for the back, because ink marks tend to be obscured during the lengthy separation process. There was fibrous and cartilaginous adherence of the thoracic cages, and care was taken to separate these without entering the pleural cavities. The two hearts were normal and unaffected. On entering the abdominal cavity, we identified a large segment of conjoined liver. This was separated, the posterior component was incised and separated, and one baby was moved onto another operating table for closure.

The incision on the baby with more fascia and skin was closed with an inferior fasciocutaneous flap (Fig. 14-19, B). Closure was effected transversely just below the costal margin. This was a secure fascial closure as well as an adequate skin closure. Relatively large dog-ears were left laterally to be addressed later, at the time of cleft lip and palate closure. The twin with the lesser amount of fascia and skin (Fig. 14-19, C) posed a more difficult reconstructive challenge. We were able to mobilize the fascia over the lower abdomen to achieve a secure abdominal wall closure. The fascial defect over the liver was closed with SurgAssist and covered with a large transposition flap from the lower abdomen.

The children were then returned to the PICU and extubated 48 hours after surgery. They were transferred to the pediatric surgery ward on postoperative day 4. They remained hospitalized for an additional 2 weeks. Normal feeding was undertaken within 1 week, and wound healing progressed satisfactorily. Distally, a 2 cm area of necrosis was present on the transposition flap, which healed with adequate nutrition, wound care, and patience.

Both babies recovered in a home setting for an additional month. They were returned to the operating room at 8 months of age for cleft lip and palate repair. Six weeks later they were discharged home (Fig. 14-19, *D*).

Ischiopagus Twins

A late-term ultrasound examination performed on a patient in Trinidad revealed a set of conjoined twins united at the pelvis. These ischiopagus twins were born without incident by cesarean section. They were healthy boys with two legs each but shared a single penis. The site of union was just caudal to the umbilicus. The classification for this set of twins was tetrabrachius, tetrapus, ischiopagus conjoined twins (Fig. 14-20, *A*).

A multitude of diagnostic tests were performed, including ultrasonography, CT scanning, standard radiographs, and barium studies of the gastrointestinal tract. The gastrointestinal tracts were separate up to the foramen cecum, at which point the bowel was united. Genitourinary studies demonstrated that one kidney drained through a ureter into the other baby's bladder. There was a single large bladder with a central partially formed septum. Each baby had intraabdominal undescended testes. The penis was shared but had four corpora. This was important, because it allowed separation of the penis into two structures. In certain sets of ischiopagus conjoined twins, the shared penis has only two corpora and cannot be divided. In one other case of ischiopagus twins in which the penis had only two corpora, we elected to create a neovagina using sigmoid colon to gender-convert one of the boys to a girl. We have had one case in which the gender-converted boy to girl opted for remasculinization of her genitalia when she became a teenager.

In this set of ischiopagus twins we elected to place five subcutaneous tissue expanders and two intraperitoneal tissue expanders to provide skin and soft tissue coverage for the abdomen and pelvis.⁴⁷ The intraabdominal expanders were placed through a posterior flank incision. The babies also required a colostomy, because there was no anal orifice. The tissue expander was inserted at the Port of Spain General Hospital by the senior surgeon, and inflation of the expanders was performed by the local plastic surgeon. Expansion progressed satisfactorily. After 6 weeks, feeding became difficult because of the enlargement of the intraabdominal expanders. Frequent small feedings were necessary to maintain nutritional support. Three months after tissue expander insertion, the children were transported to our hospital for further assessment, diagnostic procedures, and definitive separation surgery (Fig. 14-20, *B*). As is always the case with ischiopagus twins, CT revealed that the infants shared a single pelvic ring. Both the upper and lower extremities were normal. Detailed planning sessions were carried out so that each service knew the problems and concerns of the others. A run-through procedure was performed.

After positioning the patients and induction of anesthesia, our markings were made and traced with a stapler to ensure that they were not rubbed off during the first part of the operation. Ventilation of the lungs was difficult because of the large intraabdominal tissue expanders; these were removed at the start of surgery. The large bowel was separated into two segments. The urologic structures were separated accordingly, and the aberrant ureter was reinserted into the appropriate bladder. The corpora were separated and each child given a reconstructed penis. The orthopedic surgeons then performed pelvic osteotomies to form two separate pelvic rings. Each pelvis had two limbs from the appropriate baby. The final incisions were made on the back, and the twins were separated and placed on separate operating tables.

The reconstructive component was quite difficult and complex, because it required pelvic support, abdominal support, and skin coverage. Our intraabdominal expanders were effective in providing expanded tissue for pelvic support and abdominal support. Of particular importance was the capsule that had formed from the intraabdominal expanders. This was effectively used for abdominal support and complete closure in one of the children. The other child required a Marlex patch to complete closure. The skin flaps were then positioned and closed.

The large incisions from the chest expanders were somewhat dusky at the tip. The babies were then transferred to the PICU, where they remained intubated for 48 hours. Seventy-two hours later they were transferred to the pediatric surgery ward. The skin flaps had crossed the midline, and concern about their vascularity was noted. Each child eventually required a small, split-thickness skin graft on the chest wall once the flaps demarcated and were debrided with appropriate wound care. The small open areas healed uneventfully, and a favorable outcome was achieved (Fig. 14-20, *C* and *D*). One concern that did become a problem later in life for the boys was the positioning of the penis and scrotum. In both babies it was necessary to make this position quite inferior and caudal. However, both boys had effective normal micturition, and limb and pelvic growth seem to have been quite normal (Fig. 14-20, *E*).

Fig. 14-20 A, Tetrabrachius, tetrapus, ischiopagus conjoined twins shortly after birth. B, The twins are shown at approximately 3 months, after inflation of intraabdominal and subcutaneous expanders. C and D, The twins are seen postoperatively. E, Late result approximately 6 months after surgery.

Composite Tissue Transplant in Ischiopagus Twins

An ultrasonographic evaluation at 24 weeks' gestation revealed ischiopagus conjoined twins in an otherwise healthy 38-year-old woman. The babies were delivered by cesarean section at 36 weeks' gestation and then transferred to The Hospital for Sick Children in Toronto for care. They appeared to be healthy sisters, with union from the lower chest to the suprapubic region. Each had two normal upper extremities but only one normal lower extremity. There was a single pelvic ring with an additional third lower extremity, which was small, hypoplastic, deformed, and exhibiting minimal function. Thus these twins would be classified as tetrabrachius, tripus, ischiopagus conjoined twins (Fig. 14-21, *A*).

Further cardiac investigations confirmed a severe anomaly in twin A that consisted of a double-outlet right ventricle, a very restrictive ventricular septal defect and atrial septal defect, and pulmonary hypertension. CT scans and MRIs were carried out and demonstrated a shared liver with a separate biliary drainage system for each baby. There was a large urogenital sinus with one functioning kidney in twin A and two functioning kidneys in twin B. However, the right kidney in twin B demonstrated ureteropelvic junction obstruction with a greatly dilated renal pelvis. As has been noted in previous ischiopagus cases, the functioning kidney in twin A drained into the bladder of twin B.

The gastrointestinal tracts were separate until the distal ileum, as is commonly the pattern in ischiopagus twins. A reconstructed three-dimensional CT scan of the pelvis clearly demonstrated the pelvic ring as well as three hip joints and one symphysis pubis.

Elective tissue expansion was planned to start at 6 months of age. However, at 3 months of age, twin A developed acute cardiac decompensation. Several cardiologists and cardiac surgeons were consulted and felt that twin A would succumb to her cardiac anomaly within the next few days, and salvage of any kind was impossible. The cardiac anomaly in twin A was lethal and inoperable and necessitated urgent separation if twin B were to survive. After discussions with the children's family, ethicists, religious leaders, social workers, and team members, the decision was made to proceed with the separation, anticipating the demise of twin A either intraoperatively or shortly thereafter. Plans were made to transplant the normal leg of twin A onto the surviving twin B (Fig. 14-21, *B*).

The procedure began with the anterior abdominal wall incision. The hepatobiliary systems were separated, as were the gastrointestinal and urinary tracts. Twin B retained the gastrointestinal tract in continuity to the anus. We then identified the sciatic nerve coming from twin B to the third shared deformed limb. The nerve was transected and coapted to the sciatic nerve going to the transplanted limb from twin A. We preserved a portion of the myocutaneous tissue on the third shared limb to provide for active hip flexion and knee extension. The anterior thigh mass would be piggybacked on to the anterior thigh of the transplanted limb to allow hip flexion and knee extension. The femoral and iliac vessels, as well as the femoral nerve to this thigh mass coming from twin B, were left in continuity, providing an independently perfused and independently innervated myocutaneous flap of anterior thigh mass.

The pelvic osteotomies were done in such a way as to preserve the symphysis pubis between the two healthy hip joints and to create a single pelvic ring, with elimination of the hip joint from the third shared limb. The separation was complete and the transplanted limb was rotated posteriorly relative to twin B to create a single pelvic ring with two hip joints on either side of the symphysis pubis. The transplanted limb was then revascularized, with the aorta and inferior vena cava from twin A being anastomosed in an end-to-side fashion to the aorta and inferior vena

cava of twin B just below the level of the renal vessels. The stump of the sciatic nerve from twin B, which had previously innervated the third shared limb, was coapted to the sciatic nerve of the transplanted limb that had previously been innervated by twin A (Fig. 14-21, C and D).

After revascularization and reinnervation of the transplanted limb, the myocutaneous flap was sutured to the quadriceps tendon of the transplanted limb. The abdominal and chest flaps were trimmed and adequate fascial support was provided to the abdomen and pelvis of twin B.

Continued

Fig. 14-21, cont'd E, Twin B recovered full sensation in the transplanted limb and had excellent movement. F, Knee extension. G, Hip flexion. H, Plantar flexion. I, Toe movement. J, Limb function has been completely integrated into her normal cerebral function. K, Patient at 6 years of age.

Twin A died shortly after the separation. Twin B was transferred to the PICU, where she remained before being transferred to the pediatric surgery ward. There were no wound-healing problems, and she was discharged home 3 weeks after the separation. She required some minor revision surgery at 33 months of age to reposition the abducted transplanted limb by a femoral osteotomy and to tighten the tendinous insertion of the myocutaneous flap. Simultaneously, the abdominal scar was revised (Fig. 14-21, *E*).

The limb has continued to grow in proportion with the child. She has recovered full sensation to the transplanted limb and has regained excellent movement (Fig. 14-21, *F-I*). The transplanted limb appears to be completely integrated into her normal activities with appropriate voluntary movement on command and spontaneous activity with ambulation (Fig. 14-21, *J* and *K*). It is interesting that the Tocci brothers referred to earlier in this chapter were not able to achieve this, because their cortical-neural connections were separate and thus not integrated.

• • •

The original kidney transplant performed by plastic surgeon and Nobel laureate Joseph Murray used the immunocompatibility of identical twins for its success. Similarly, in conjoined twins, tissue can be transplanted from one twin to another, thus affording numerous transplant opportunities. In this section we have seen the role of kidney transplantation in conjoined twins and split-thickness skin grafts crossed between one twin and the other. In the last case, an entire lower extremity was transplanted from one twin, who was destined to succumb to her cardiac anomaly, to her surviving sister, who would otherwise have had only one leg.

CONCLUSION

These case examples illustrate several principles in conjoined twin separation. First, one should have as much information as possible before undertaking separation surgery. This not only involves detailed evaluations but also may include examinations with the patient anesthetized.

In these complex procedures it can be anticipated that wound-healing problems will arise. Adequate nutritional support is essential, as is intensive care monitoring and support. In one of our ischiopagus twin separations (not reported here), a large area of exposed abdomen was present in one baby. Without intensive care support, this baby surely would not have survived. Patience is extremely important in these cases. Time and adequate nutrition will provide the essentials for wound healing. We have learned not to rush into reconstructive procedures for secondary wound issues but rather to allow granulation tissue to form and then proceed with simpler procedures, such as skin grafting.

We have also learned that even expanded skin flaps do not do well if they cross the midline in conjoined twins. The vascular connections do not cross the midline, and thus one cannot expect large flaps to survive if they are based on the midline. Care in planning and in insertion of tissue expanders is essential.

We have seen that sex change procedures in conjoined twins are not as effective as one might expect. We opted to carry out a sex change procedure in one child, which probably would have been better approached with a penile reconstruction at a later date.

The value and importance of multidisciplinary planning and the involvement of all team members are crucial in conjoined twin separation surgery. This includes team members from anesthesiology, intensive care, and the various subsurgical specialties involved as well as psychologists, ethicists, and particularly social workers. Support for the family is imperative during these complex and high-risk procedures.

The separation of conjoined twins should not be undertaken lightly by any institution. Expert support in all areas must be present, and a coordinated team effort is essential. The risks are high, but the results can be extremely gratifying for the professionals involved and, of course, for the parents, families, and children involved.

KEY POINTS

- It is essential to gather as much information as possible before separation surgery is undertaken.
- The surgical team should be patient and anticipate secondary wound healing.
- The twins' nutritional status needs to be maximized before separation.
- PICU support is essential.
- The site of twin union must not be crossed in flap design and reconstruction.
- Sex alteration should be avoided.
- This is a complex procedure requiring a full team of experts.
- Surgical planning is paramount, and a surgical rehearsal can be valuable in multidisciplinary surgeries.

Soft Tissue Trauma

Andreas M. Lamelas • Peter J. Taub

Young children sustain a disproportionate number of soft tissue injuries to the head and neck region compared with the incidence in adults, largely because of children's curiosity, lack of caution, and still-developing vestibular sense (balance). The mechanisms of injury typically seen in children include falls, sporting activities, motor vehicle collisions, interpersonal violence, and abuse, with the frequency of each cause differing between age groups. In 2010, head, face, and neck injuries to children under the age of 15 accounted for 3.6% and 1.8% of all emergency department visits in males and females, respectively.¹

Because of the rapid growth of their brains, a child has a relatively large head compared with the rest of his or her body, making this area very susceptible to injury. The introduction of several governmental safety regulations, including mandatory airbags, the use of seat belts, child seats, helmets, and mouth guards, has directly led to a decrease in head and neck injuries, but even with such safeguards in place, significant soft tissue injuries occur and present a real challenge to the plastic surgeon. These challenges are often compounded by the potential adverse effects the injury may have on the future growth of the child, both physically and mentally. The face represents the most important presenting part of the body and plays a major role in psychological development. An unfavorable outcome may have drastic effects on the child's interpersonal relations and self-esteem. As a result, counseling of both the patient and the parents is often as important as the surgical treatment of the injury. To successfully manage pediatric soft tissue and maxillofacial injuries, the clinician must have a firm grasp of the physiologic and psychological principles associated with facial injuries.

The goals of management of facial trauma in all age groups are to restore and preserve function while achieving optimal cosmetic results and minimizing scar formation. The pediatric

population requires modified therapies to accommodate their unique differences, including anatomy, rapid healing, fragile psychology, and the potential for future deformity in relation to altered facial growth. Although usually minor in nature, soft tissue injuries are the most common facial injuries in children, encompassing a spectrum that includes bruising, abrasions, lacerations, avulsions, and burns. Fortunately, most of these injuries can be repaired in the emergency department or office with the use of a local anesthetic, but general anesthesia should not be avoided if it will facilitate a better end result.

PATIENT ASSESSMENT AND MANAGEMENT

The evaluation of all patients with head and neck injury should begin with the ABCs of trauma to confirm that the patient has an adequate airway, is breathing appropriately, and is maintaining systemic circulation. Emergent airway stabilization is rarely required with isolated soft tissue injuries, but the need for tracheostomy in these patients with no concomitant skeletal injury is associated with high mortality rates. Craniofacial injuries are identified after the patient is stabilized, and the patient is assessed for intracranial, ophthalmologic, and cervical spine injuries.² Children are often frightened of medical personnel, and the initial contact should focus on gaining trust, reassurance, and achieving mutual cooperation.³

A detailed history should be obtained to determine the nature of the soft tissue injury and the likelihood that there are underlying fractures. If an embedded foreign body or associated maxillofacial fracture is suspected, radiographic studies are indicated. Although plain films may be helpful, such as an orthopantomogram or oblique views of the mandible, CT scanning is the mode of choice to evaluate not only the osseous structures but also the soft tissue. Severe maxillofacial injuries warrant a CT scan of the brain, which allows the team to obtain maxillofacial cuts for clear definition of skeletal injuries.

Soft tissue injuries are classified by the cause, location, size, depth, extent of soft tissue loss, and any important structures involved. Photographs should be taken with the parent's consent to document the injuries. Pretreatment and posttreatment photographs can be very important for addressing insurance, child abuse, and medicolegal issues. If child abuse is strongly suspected, the appropriate authorities must be notified and clinical findings documented in the patient record.

Patient cooperation with a pediatric injury may be difficult. It is essential to have the child calm and motionless so necessary treatment can be provided. Some children do well with gentle reassurance and parental support, but the use of sedation may be necessary in certain circumstances. Infants usually require the presence of a parent as a soothing influence for evaluation. Older children may be calmed with distraction, such as a video on a handheld tablet. Adolescents may benefit from asking the parent to leave the treatment area. Many institutions employ child-life specialists to assist with the care of pediatric patients. Before any intervention, the patient and parent should be informed of the proposed plan, and realistic expectations should be established to allay surprise or dismay after the repair. This includes education on postoperative care, the healing process, and eventual scarring.

Analgesia may be obtained with one or more medications before the repair begins. If necessary, sedation may be safely achieved with agents such as ketamine or propofol. The use of such agents requires close monitoring of the patient's vital signs and avoidance of unintended general anesthesia. If sedation is required, the timing of the patient's last meal should be noted to help prevent aspiration. Most soft tissue injuries in children can be managed in the emergency department, but in certain circumstances, such as the treatment of large wounds or injuries that have disrupted delicate structures, general anesthesia in the operating room may be more appropriate.

For all major injuries, local anesthetic should be administered before wound cleansing and exploration. To minimize the discomfort of an injection, a local anesthetic should be administered

through the margins of the wound rather than into the surrounding skin, and topical anesthetics such as lidocaine/prilocaine (EMLA) are available to further decrease the pain of injection. Regional nerve blocks are very useful in larger injuries, especially those involving the forehead, cheeks, lips, and chin. These blocks minimize the tissue damage and anatomic distortion created from direct injection into the wound. The forehead can be blocked by direct injection of the supratrochlear and supraorbital nerves bilaterally, located just above the superior orbital rim, 1.7 and 2.7 cm from the midline, respectively. The upper lip, lateral nasal wall, and cheek are blocked with injection of the infraorbital nerve, located 4 to 7 mm below the infraorbital rim in line with the medial limbus. The lower lip and chin are blocked with bilateral injection of the mental nerve, located below the apex of the second bicuspid.⁴

After appropriate anesthesia is administered, a detailed inspection of the wound should be performed to identify all structures involved and the presence of any foreign material. Any foreign material must be meticulously removed to prevent future cosmetic deformity, such as tattooing. Devitalized areas should be debrided judiciously to maximize preservation of available tissue. The rich blood flow of the face allows a significant amount of injured tissue to survive, even with a seemingly small vascular bridge. Copious irrigation allows most wounds to be closed immediately, with low rates of infection. In patients with significant tissue loss or gross contamination, a delayed repair may be indicated.

The planning and execution of proper skin closure in pediatric patients is imperative to improve the final outcome. This involves appropriate debridement and irrigation, accurate repositioning and alignment of affected tissues, and the use of the correct closure material. Injuries that extend across the margins of the lips, nostrils, eyelids, or external ears may benefit from tattooing before manipulation to facilitate exact anatomic alignment during closure. In general, deeper tissues, including muscle, fascia, and subcutaneous fat, are closed with absorbable sutures. Closing deeper tissues decreases tension on the skin and minimizes scar formation. Skin closure should be performed with the knowledge that suture removal can be an equally traumatic event for the patient. Many options are available, and the decision is left up to the surgeon. Options include the use of fast-absorbing catgut suture on the skin, placement of subcuticular sutures with overlying tissue adhesives (DermaBond) or Steri-Strips, and recently, the use of pull-through monofilament sutures followed by tissue adhesive application after suture removal. The use of staples is an effective method for wound closure but should be reserved for injuries to the scalp.

TYPES OF INJURY

Hematomas

Hematomas are a sequela of a blunt trauma that has caused rupture of dermal or subdermal blood vessels and can often indicate a more significant underlying bone injury. Small hematomas often resolve with warm compresses and observation; however, large hematomas may require aspiration with a fine needle 7 to 10 days after injury once liquefaction occurs.⁵ Hematomas near the septal and conchal cartilage require specific mention; these will be discussed in their respective sections. Delayed hematomas may not be easily aspirated and if large may need operative evacuation.

Abrasions

Mechanical abrasions represent partial-thickness skin injury and vary in thickness. *Superficial abrasions* localized just to the epidermis should be thoroughly cleaned and covered with nonadhering dressings, such as antibiotic ointment or Xeroform gauze. To adequately cleanse the wound, local anesthesia may be required to reduce pain. Superficial abrasions will heal without a permanent scar with proper cleansing and local wound care. *Partial-thickness abrasions* extend into the dermis.

Conservative management for partial-thickness injuries is paramount and includes judicious debridement of devitalized tissue and scrubbing with antimicrobial soap to remove debris.⁶ Most partial-thickness abrasions will heal with minor scarring. *Full-thickness abrasions* extend through the dermis and into the subcutaneous tissues. These injuries are a result of a significant blunt trauma and should be an indicator that other serious injuries may be present. After proper wound debridement and copious irrigation, primary closure is performed when possible. Although local advancement flaps are often needed to properly achieve wound coverage, the wound should be given time to demarcate in case additional debridement is needed. In all cases it is very important to remove embedded material to prevent permanent tattooing. For full-thickness injuries, antibiotic coverage is strongly recommended.

Lacerations

Facial lacerations can vary significantly, depending on location, size, depth, and associated injuries. At first glance the laceration may seem small, but such injuries often extend deeper and can affect both sensory and motor nerves, the parotid ducts, lacrimal ducts, and other critical facial structures. All lacerations must be thoroughly irrigated, inspected, and properly debrided, usually requiring a combination of anesthetic techniques, depending on the age and affect of the child. Injuries that extend across margins, such as the lips, nostrils, eyelids, or external ears, require particular attention, because even small defects in alignment will be readily noticeable. Periorbital injuries should prompt a thorough eye examination and an ophthalmology consultation to rule out ocular injury.⁶

In general, facial lacerations should be debrided minimally to maximize tissue preservation and allow primary closure. Superficial lacerations require closure of just the dermis and epidermis. A well-approximated deep dermal layer with fine absorbable sutures is essential to decrease skin tension and prevent scar widening, although one study found that superficial, nongaping (less than 10 mm) linear lacerations can be closed in one layer with similar cosmetic results.⁷ The surgeon has many options for skin closure, including absorbable and nonabsorbable sutures or tissue adhesives. Traditional teaching recommended the use of nonabsorbable sutures, because they are minimally reactive and maintain good tensile strength. However, their main disadvantage is that they need to be removed, which can be very difficult and even damaging in a young or very anxious patient. Recent studies assessing both absorbable sutures and tissue adhesives (DermaBond) have found that they are equally effective and provide the same cosmetic results.^{8,9} For deeper lacerations, a layered closure is important to reapproximate functional muscle or fascial planes. Muscle, fascia, and subcutaneous sutures should be a fine absorbable material, such as Vicryl or PDS. Mucosal defects are usually closed with chromic gut, but some surgeons recommend Vicryl, because it is less irritating to the patient. Two of the most common complications of a primary facial closure are infection and hematoma. For this reason, meticulous attention to hemostasis and copious irrigation are crucial before final epidermal closure.

Postoperative care of facial lacerations is often debated and is ultimately up to the surgeon. Topical antibiotic ointments have been found to not only decrease wound infections but also to provide a moist environment to promote epithelialization. Additional covering has not been found to decrease infection or improve healing. It has been noted that patients can get the wound wet after 12 hours with no increase in infection rates.¹⁰

Avulsions

Blunt trauma that produces a variable thickness flap of skin with or without underlying tissue constitutes an *avulsion*. In the acute setting, the simplest repair should be chosen. Questionably viable tissue should be preserved if excision would prevent primary closure. Closure should be

done with essentially no tension. Recruiting local tissue flaps in an acute situation often results in further ischemia and necrosis because of the disruption of local circulation. Wounds with extensive soft tissue loss should be treated with local wound care and serial debridement every 24 to 48 hours to establish viable wound edges. Final closure should only be performed after all remaining tissue is viable with no signs of infection.⁵

Many soft tissue defects in the face can be repaired with local rotation or transposition flaps. Large pedicled flaps and free tissue transfer may also be required in cases of significant loss, but rarely in the emergent setting. When skin grafting is required, special consideration must be given to the choice of donor site. Patient age and sex as well as graft thickness should be considered. Skin from hair-bearing sites should be avoided unless specifically indicated. For large, split-thickness grafts, the lateral thigh, buttock, anterior abdominal wall, medial thigh, and medial upper arm are reasonable choices. For smaller areas, when a full-thickness graft is required, the cervical, preauricular, and postauricular skin is preferred for its color match.²

Dog Bites

An estimated 4.7 million people sustain dog bites annually, with most occurring in the pediatric population, leading to more than 400,000 emergency department visits every year.³ Although bites can occur anywhere on the body, in children approximately 80% involve the head and neck because of a child's similar size in relation to the animal. The most common sites involved are the cheeks, lips, nose, and ears.¹¹ Although most of these bites can be treated with primary closure, the immense force of the bite can lead to more severe injuries, including complex soft tissue avulsions, facial fractures, or injuries to the airway or major blood vessels. In addition, even if the bite appears to be an isolated laceration or avulsion, there is often a crush injury component that may require further investigation. The severity of the injury increases in infants and younger children because of their smaller size and thinner tissues.¹² Regardless of the extent of the injury, medical management should include tetanus prophylaxis, prophylactic antibiotics, and rabies precautions (Fig. 15-1).

Fig. 15-1 A, A boy with a dog bite to the face. B, After careful wound care and closure, the patient appears to be doing very well. Although the scars are permanent, they will improve with time.

Wild animals must be considered rabid, and if possible, the brain of the offending animal should be examined for the presence of rabies antibodies. The patient should be treated with prophylactic rabbit immune globulin and human diploid cell rabies vaccine (HDCV) when indicated. If HDCV is not available, duck embryo vaccine may be substituted. If the bite is from a nonimmunized or questionably immunized domestic animal, the animal may need to be quarantined for 10 days, and if no illness or odd behavior is observed in the animal within this period, no treatment of the child is required.¹³

The rate of infection from dog bites ranges from 10% to 15%, with *Pasteurella multocida* and *Staphylococcus aureus* the two most common organisms involved.¹⁴ Antibiotic prophylaxis is commonly administered, especially in immunocompromised patients or those with contaminated wounds or wounds with delayed healing. Initial choices include oral amoxicillin or ampicillin with sulbactam for more severe cases requiring parenteral administration. For patients with a penicillin allergy, options include an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin for anaerobic coverage. The length of antibiotic therapy can vary from 3 to 14 days, based on clinical judgment.¹⁵

On initial evaluation, the wound should be copiously irrigated with a mixture of normal saline solution and either a surgical preparation solution or an antibiotic solution. Cleansing should be followed by a thorough inspection to identify all injuries, with an awareness that both the upper and lower jaws of the dog may have caused damage. Debridement of facial wounds must always be minimal, but devitalized and shredded tissue should be removed to create a viable wound margin for closure. Irregular margins may be used to create a broken line for closure, reducing the need for unnecessary debridement of viable tissue. For cosmetic concerns, all dog bites to the face should be closed primarily if possible. Wounds with a very high possibility of infection or those more than 12 hours old should undergo delayed primary repair. In the event of significant soft tissue loss or underlying bone injury, the patient should be taken to the operating room for repair. Local tissue flaps and skin may be necessary for coverage, but these should not be placed over infected or contaminated wounds in the acute setting because of the increased risk of infection (Fig. 15-2).

Fig. 15-2 A, A child with a dog bite to the face treated with primary closure and local flaps. B, The patient shows normal animation of the face with residual scarring.

Thermal Burns

Burn injury is the fifth leading cause of accidental death in children, with thermal burns representing two thirds of all cases. Recent improvements in resuscitative measures, infection control, wound care, and nutritional measures have greatly increased survival.¹⁶ Although the pathophysiology and management principles of thermal burns are similar in children and adults, certain differences exist, including specifics of acute resuscitation, wound healing, derangements in facial growth, and increased emotional and psychosocial effects.¹⁶ A multidisciplinary approach with a well-thought-out plan is crucial to a successful functional and cosmetic outcome.

Thermal burns are caused by direct cellular destruction from thermal energy. The extent of damage is based on both the temperature and duration of exposure. Burns are classified based on the depth of injury. *First-degree burns* are limited to the epidermis and heal within 1 week with no residual scarring. *Second-degree burns* extend into the dermis and are further distinguished by the depth of dermal involvement (superficial versus deep). A superficial second-degree burn will heal within 1 to 2 weeks, but a deeper second-degree burn may take over 1 month to heal. *Third-degree burns* extend completely through the dermis into the subcutaneous tissues, causing loss of sensation as a result of local nerve injury. *Fourth-degree burns* are characterized by exposed muscle or bone. In general, deep second-degree burns and deeper burns require early excision and grafting. Children have thinner tissues than adults, which puts them at increased risk of more severe burns, and thus a child with a burn injury that appears similar to that of an adult may actually have more damage.¹⁷

First-degree burns are best treated conservatively, with localized care and bacitracin ointment. Superficial second-degree burns are also treated with antibiotic ointment (bacitracin or silver sulfadiazine) and subsequent coverage with a moist, semioclusive dressing. For auricular burns, mafenide acetate (Sulfamylon) is the preferred topical antibiotic, because it penetrates down to the cartilage and gives excellent coverage for *Pseudomonas* infection. For deeper burns, there are three phases of injury management: cleaning and debridement, tissue grafting, and reconstruction. The first phase lasts about 7 to 10 days and consists of topical antibiotics and local debridement to allow tissue demarcation before proceeding with excision and grafting. Skin substitutes, such as cadaveric allografts, xenografts, or a bioengineered membrane such as Integra, can be used for temporary coverage before definitive repair. Final reconstruction should start at least 1 year after injury to allow complete graft healing and scar maturation.

The healing process for burn injuries is often complicated by scar contractures, leading to multiple complications in the growing child. Periorbital contractures resulting in lid closure can be complicated by occlusion amblyopia, which is a loss of vision resulting from interruption of the developing visual axis. Perioral burns can cause microstomia, difficulties with speech and feeding, and alteration in dentition.¹⁸ Facial growth is also greatly influenced by symmetrical external forces from surrounding tissues, and alterations in these forces from scarring can lead to deformity. This is especially likely in the developing nose, which can be limited by surrounding contractures.

A discussion of all the reconstruction options for facial burns is beyond the scope of this chapter, but the key to a successful outcome is reconstruction based on specific facial aesthetic units. When multiple procedures are required, the recommended sequence for reconstruction is:

1. Perioral tissues
2. Neck, chin, or cheek
3. All remaining tissues

Treatment of pediatric burns remains a very difficult area for the plastic surgeon. Reconstruction is often a long-term process requiring a strong relationship between the surgeon and patient.

Electrical Burns

Electrical burns account for 4% to 7% of total burns, with many of them seen in young children who bite on electrical cords.¹⁹ The lower lip and lateral commissures are most often affected, but the teeth and supporting structures may also be involved. The extent of injury depends on the voltage, duration of contact, tissue resistance, and type of current. Household alternating current (AC) produces more damage than direct current (DC) of the same voltage.²⁰ The burn cauterizes local blood vessels and nerves, resulting in a painless necrotic lesion with minimal bleeding. Supportive care includes tetanus prophylaxis, administration of fluids, and antibiotic coverage. After initial eschar separation, secondary wound healing begins, usually resulting in significant scarring and microstomia.²¹ Early oral splinting is very important in this phase to prevent the formation of contractures. Oral burns can also affect craniofacial growth and development; therefore orthodontic appliances may be warranted in some patients to maintain growth.¹⁹ Reconstruction planning should begin once the healing process is complete. The hallmark of proper oral reconstruction is overcorrection to allow the inevitable postoperative wound contraction.

SPECIAL CONSIDERATIONS

Scalp Injuries

The scalp has an extensive vascular supply, which can produce significant blood loss when injured. Immediate application of a compression bandage will facilitate hemostasis before closure. The scalp consists of five layers: (1) skin, (2) subcutaneous tissue, (3) galeal aponeurosis (galea aponeurotica), (4) loose areolar tissue, and (5) periosteum. In general, most defects under 3 cm can be closed primarily, with or without galeal scoring.² Attempts should be made to close the scalp in layers, especially the strong galeal aponeurosis, which permits better skin approximation and helps prevent future development of a subgaleal hematoma. If time does not permit a layered closure, adequate control of hemorrhage and closure can be achieved with a single layer of running, interlocking sutures or staples. Any large arterial bleed identified should be suture ligated before closure. Associated skull fractures must always be suspected, and the surgeon should perform thorough palpation and inspection for any full-thickness scalp wound.

Eyebrow Injuries

Eyebrow lacerations should not prompt one to shave the remaining hair because of the unpredictable ability of the hair to grow back. The hairs of the eyebrow run oblique to the skin surface, so any additional incisions made for further debridement should follow the line of the eyebrows to limit hair loss. Lacerations should be closed meticulously in layers, including any muscles involved, with careful alignment of the superior and inferior margins. Approximation of the superior border takes priority, because misalignment in this area is most noticeable.³

Eyelid Injuries

In all traumatic eyelid injuries, the first priority is to rule out and avoid ocular injury. A topical anesthetic may be used to help with the examination and facilitate closure. A corneal shield may be used to avoid injury to the cornea. Full-thickness lacerations must be repaired by separately approximating each layer involved, beginning from deep (conjunctiva) to superficial (skin). A fine absorbable suture is used to carefully close the conjunctiva, avoiding corneal injury or irritation from the suture knots. The tarsal plate should be separately repaired with similar

absorbable suture. If the insertion of the levator aponeurosis or Müller's muscle is disrupted, it should be properly advanced to the tarsal plate at the time of repair to prevent later ptosis. The skin is closed with either absorbable or permanent interrupted or running sutures. Permanent sutures may be removed within the first week to minimize scarring. It is important to accurately align the gray line to restore the normal curvature of the eyelid margin. Any injury to the lower lid poses a greater risk of increased scleral show and ectropion formation. Although proper tissue realignment during repair decreases the risk of such complications, in some patients cartilage grafting, lateral canthopexy, or tarsal strip grafting is required to provide additional support.²²

Avulsion of the eyelid is a true surgical emergency. Immediate coverage is required to prevent further corneal damage, decreased visual acuity, and exposure keratopathy. On initial evaluation in the emergency department, an antibiotic patch should be placed over the cornea and the eye covered with a nonpermeable occlusive eye shield. Trapping moisture within the orbit helps to prevent dryness and further desiccation of the superficial corneal layers. An ophthalmologist should be consulted in all cases. Various reconstructive techniques have been described, with the common goal of replacing all three layers of the lid to restore function. The conjunctiva can be replaced with adjacent or cross-lid conjunctiva or conjunctival grafts consisting of oral or palatal mucosa. The tarsus is reconstructed by tarsal plate advancement or nonvascularized cartilage grafts, and skin is replaced with local tissue flaps or full-thickness skin grafts.²³

Lacrimal Duct Injuries

Lacrimal duct injuries occur in 16% of eyelid lacerations from either penetrating or blunt trauma.²⁴ Lacerations involving the medial canthal region are assumed to have an associated lacrimal duct injury. In most cases visual inspection of the wound will reveal the injury, but probing can be performed to confirm the diagnosis. Care must be taken to avoid exacerbating the injury during inspection and repair. If both ends of the ducts can be identified, the severed ends should be realigned, splinted internally, and repaired over a Silastic tube, which is generally left in place for 3 to 6 months. Some surgeons have elected not to directly repair the mucosal injury of the duct and have shown equivalent results repairing only the surrounding soft tissue to bolster the stent.²⁵

Nasal Injuries

The soft tissue of the nose includes the skin, subcutaneous fat, nasal muscles, cartilage, and endonasal mucosa, all of which are highly susceptible to injury as a result of the anterior projection of the nose from the face. All soft tissue injuries, including lacerations and avulsions of the nose, have the potential to cause both functional and cosmetic problems either as a result of tissue loss or poor healing. Intervention should be initiated as early as possible, beginning with judicious debridement, irrigation, and definitive repair. Full-thickness injuries should be repaired in layers. Nasal mucosa should be repaired with fine absorbable suture. Cartilage and skin should be approximated with fine nonabsorbable interrupted sutures, although in younger patients absorbable sutures or tissue adhesives may be more effective for skin closure.

The nose has multiple aesthetic units, including the tip, dorsum, paired alae, nasal sidewalls, and soft triangles. Each should be carefully addressed and reapproximated during the repair.²⁶ Significant cosmetic landmarks, such as the epidermal-mucosal junctions, nasal fold junctions, or alar rims, should be aligned first to decrease the likelihood of asymmetry.

Complications specific to the nose include nasal vestibular stenosis, with resultant airflow obstruction and chondromalacia of the nasal cartilage. Scarring and contracture of the alae cause obstruction after injury, and chondromalacia results from an untreated septal hematoma and can

eventually lead to a saddlenose deformity. If a septal hematoma is diagnosed, drainage should be performed immediately.²⁶

Cheek Injuries

The cheek is defined as the area bordered by the infraorbital region superiorly, the nasolabial fold medially, and the preauricular area laterally. The area consists of multiple important structures; therefore a comprehensive head and neck examination must be performed for all injuries. If the injury extends into the oral cavity, a layered closure is required, with fine absorbable sutures used for the mucosa and muscle layer and then either absorbable or nonabsorbable sutures for the skin, depending on the age of the child.³ Cheek lacerations may result in damage to the facial nerve; this will usually be evident during the head and neck examination. If the nerve is lacerated, a primary anastomosis should be performed during skin repair if the two ends are identified.

The parotid duct connects the parotid gland to the oral cavity, with the opening located adjacent to the maxillary second molar. If a duct injury is suspected, the orifice of Stensen's duct should be probed by injecting saline solution or dilute hydrogen peroxide through an angiocatheter, observing for communication with the wound. The use of methylene blue is discouraged, because it can cause discoloration of the tissues. If injury is confirmed, the proximal end can be identified by the expression of saliva from the gland. A catheter is then positioned through the laceration via Stensen's duct, and the duct is repaired over the catheter.²⁷

Lip Injuries

In evaluating facial appearance, the human eye is initially drawn to the lips and eyes, emphasizing the importance of these structures.²⁸ Particular care must be taken to align three important labial structures: the vermilion border, the orbicularis oris muscle, and the red line. The vermilion border and red line can be marked with methylene blue or tacking sutures to help facilitate meticulous alignment. This is especially helpful if performed before infiltration of local anesthetic, which can distort these areas.

The *vermilion border* (white roll) marks the border between the vermilion and the cutaneous skin. This structure should be the first area to be precisely approximated during closure. Two sutures, one on each side of the border, should be placed to align opposing tattoo marks or tacking sutures. Failure to properly align this structure is usually apparent from several feet away, even with a 1 mm difference. The second area to be approximated should be the red line, which forms the junction between the wet and dry mucosa of the lip. Failure to properly realign this structure results in a vertical distortion of the lip vermilion and chapping of the lip from eversion of the wet mucosa into the dry area. In general, sutures placed in the mucosa should be absorbable, and cutaneous skin sutures can be either fast-absorbable or nonabsorbable, depending on the age of the child. An interrupted or figure-of-eight absorbable suture should be used to approximate the orbicularis oris muscle. Poor reparative efforts in this area will lead to both abnormal lip movement and muscle bulging lateral to the bite area.²⁸ After repair, patients should be instructed to rinse their mouths five times daily with an antimicrobial mouthwash.

External Ear Injuries

Because of its exposed position on the head, the external ear is commonly involved in traumatic injuries. The rich vasculature of the ear allows excellent healing if properly treated, even with severe injuries. After adequate debridement of devitalized or jagged tissue, full-thickness ear lacerations should be repaired in a three-layer closure with either fine absorbable or nonabsorbable sutures for the cartilage and skin (anterior and posterior). If there is a large area of exposed cartilage without available skin coverage, this cartilage can be preserved within a subcutaneous pocket in the mastoid region for future reconstructive efforts.²⁹

Ear cartilage is very susceptible to deformity from hematoma, and thus meticulous hemostasis should be performed before closure. *Cauliflower ear* is the result of recurrent blunt trauma, causing formation of subperichondrial hematomas. These collections create a chondroinductive matrix for chondroblasts contained within the elevated perichondrium. Chondroblasts then form ectopic cartilage within the area, inducing significant deformity. Prevention includes rapid incision and drainage of any auricular hematomas. Meticulous hemostasis must be achieved, followed by primary closure. In a large hematoma, a suction drain may be left in place for several days.³⁰ If the patient has already developed this condition, the heterotopic cartilage can be directly excised through multiple approaches.³¹ A compression dressing is then applied to maintain proper tissue contour and prevent further bleeding.

Complete avulsion or amputation of the ear requires immediate microvascular repair. When successfully completed, repair typically results in full restoration of the external ear structure (see Chapter 33). Delayed management of an avulsed ear often requires total ear reconstruction. Partial avulsions may be treated with sharp debridement, followed by local tissue advancement flaps. The opposite ear or costal cartilage can be used. More significant defects require harvesting cartilage from the opposite ear and covering the free cartilage graft with a temporal parietal flap and full-thickness skin graft.

Nerve Injuries

The facial nerve is the motor nerve that is most vulnerable to both blunt and penetrating facial trauma and results in serious functional and aesthetic defects. An early, accurate examination of facial animation should be performed after any injury.³² So that all of the critical branches of the nerve can be assessed, patients should be asked to raise their eyebrows (frontal branch), close their eyes (zygomatic), smile (buccal), and pucker their lips (marginal mandibular). In penetrating injuries with transection of all or portions of the nerve, deficits will be seen immediately; however, in blunt trauma there may be a partial or delayed effect. Transection injuries that occur anterior to the lateral canthus are often only observed because of the sufficient crossover from the opposite side. If the injury is posterior to the lateral canthus, early identification and repair by direct coaptation or cable grafts will achieve the best results.³³ If there is substantial nerve loss or a grossly infected field that precludes immediate repair, the nerve ends should be identified and tagged for later repair (Fig. 15-3).

Fig. 15-3 A patient with a severe injury of the facial area, including the facial nerve. **A**, A large open wound of the cheek. **B**, The facial nerve is exposed and repaired. **C**, Resultant scar. **D**, Partial return of animation 1 year later.

Sensory nerves, such as the supraorbital, supratrochlear, infraorbital, and mental nerves, may be injured by trauma; however, the resultant hypesthesia typically causes only minimal long-term effects.

MANAGEMENT OF COMPLICATIONS

Common complications in pediatric patients are related to poor scarring (widespread, hypertrophic, hypopigmented, or hyperpigmented) or keloid formation, but hematomas and wound infections also occur and require immediate attention. Children often heal with hypertrophic scars that will flatten and fade over time. It can take more than 1 year for the redness to fade and the scar to soften (see Fig. 15-3, *C* and *D*). Because of this, revisions, when necessary, should be delayed for a minimum of 6 months, if not more than 1 year. Initial scar treatment with a pulsed-dye laser or dermabrasion may be sufficient, and the anticipated secondary surgery may become unnecessary.³ Conversely, there is no need to wait until adulthood to repair such scars, which may carry significant psychological implications and potentially have deleterious effects on development. If the patient has a history of poor scarring, techniques for prevention include triamcinolone acetonide (Kenalog) injections, pressure dressings, and limiting skin stretching along the scar. To limit skin stretching during healing and thereby facilitate appropriate wound resting, wounds should be

Fig. 15-4 An infected facial wound. Traumatic injuries are considered contaminated, with an increased risk of infection. For treatment of wound infections, sutures should be removed and the wound allowed to close by secondary intention.

covered by fixable materials, including tape, bandages, garments, or silicone gel sheets.³⁴ In addition, the use of topical steroids can help alleviate the itching associated with keloids.³⁴

Prevention is the best treatment for infections and hematomas. The use of sterile technique, administration of antibiotics when necessary, and application of proper hemostatic measures can be very effective. For acute wound infections, it is often necessary to open a portion of the wound to allow drainage of any accumulated fluid. Wound cultures should be taken, and the patient is then started on empirical antibiotics until the results of cultures and sensitivities return. The wound should remain open until the infection has resolved and can then be reclosed or allowed to heal by secondary intention, depending on the circumstances (Fig. 15-4).

Stable hematomas can be observed and treated with warm compresses, but expanding hematomas require intervention. The wound should be reopened and explored for active bleeding. Once hemostasis is achieved, the wound can be reclosed and covered with a pressure dressing for added prevention.

CONCLUSION

Facial soft tissue trauma in the pediatric population is very common and requires both proper management of the injury and appropriate handling of the patient's and parents' concerns. Early assessment and treatment of facial injuries is the key to preventing immediate complications and ultimately achieving a successful outcome. Insufficient or delayed treatment can lead to long-term disfigurement, which can have a significant impact on the patient's psychological development. Considerable attention should be given to preparing the patient and parents for the healing process and the possibility of complications, with the need for future revisions. In addition to detailed documentation of location, size, depth, and associated injuries, photographs are very important to help show progress. In the acute stages of treatment, children benefit from a more conservative approach with the simplest possible repair, with more complex procedures reserved for secondary repair. Primary closure can usually be achieved with copious irrigation, judicious debridement, and meticulous reapproximation. In cases of significant tissue loss that prevents primary closure, the wound should be optimized before reconstruction with grafts or tissue flaps.

Ultimately, the management of facial soft tissue trauma is similar for children and adults—both require mastery of the full spectrum of reconstructive techniques to restore and preserve function while achieving optimal cosmetic results.

KEY POINTS

- Evaluation of all patients with head and neck trauma should begin with the ABCs to confirm that the patient has an adequate airway, is breathing appropriately, and is maintaining systemic circulation.
- Children are often frightened of medical personnel, and initial contact should focus on gaining their trust, reassuring them, and achieving mutual cooperation.
- For all major injuries, a local anesthetic should be administered before wound cleansing and exploration to prevent unnecessary pain during the process.
- Most soft tissue injuries in children can be managed in the emergency department or office with a local anesthetic, with or without sedation, but the use of general anesthesia in the operating room may be appropriate in special circumstances.
- Primary closure can usually be achieved with copious irrigation, judicious debridement, and the use of systemic antibiotics for highly contaminated wounds, especially human or dog bites.
- For an acute traumatic injury, children benefit from a more conservative approach, using the simplest possible repair and reserving more complex procedures for secondary repair.

Injections, Infiltrations, and Envenomations

Perry J. Johnson • Jason J. Miller • Ronald R. Hollins

any injection, infiltration, and envenomation injuries appear innocuous at initial presentation, but they can result in devastating consequences if they are not promptly recognized and effectively managed. Infiltration injuries typically involve the extremities, most commonly the hand and forearm, whereas injection injuries usually involve the nondominant hand. A variety of land and sea envenomations can result in serious injury, loss of function, and death. Many envenomation injuries can be managed expectantly with local measures, although some may require surgical and emergent intervention, including antivenin.

HIGH-PRESSURE INJECTION INJURIES

High-pressure injection injuries are rare in children and frequently present as an innocuous injury, but they can result in severe morbidity, including loss of function and the need for amputation. Patients frequently delay seeking treatment. The initial assessment and treatment by medical staff may be inadequate and the destructive potential of the injury underappreciated. Significant functional limitations and amputation rates of up to 48% have been reported.¹ Injection injuries typically result from high-pressure sprayers affecting the nondominant hand. Pressures generated from sprayers can range from 3000 to 69,000 psi.² The pressure necessary to penetrate skin is only 100 psi, and higher pressures can penetrate skin without direct contact.^{3,4}

Factors that affect the magnitude of injury include the interval length from injury to treatment, the type and toxicity of the injected material, the pressure/velocity of the injection, the amount injected and its temperature, the anatomy and distensibility of the involved tissues, ma-

terial viscosity and spread, and secondary infection.⁵ Tissue destruction results not only from the mechanical trauma of a high-pressure injection, but, more importantly, from the toxicity of the injected material.

Commonly injected industrial agents include grease, fuel, hydraulic fluid, paint, and solvents. Grease and hydraulic fluid are more viscous and spread relatively less than other agents. These injuries may result in fibrosis, scarring, chronic fistula, and progressive loss of function. Paints, thinners, and solvents have a lower viscosity and spread more easily. These agents tend to create a much more vigorous inflammatory response than grease or hydraulic fluid. A negative synergistic effect may result from the mechanical and chemical injuries, leading to severe edema and vascular compromise. Unless injuries are recognized and treated early, tissue necrosis can result, necessitating amputation.

Authors agree that the degree of tissue damage correlates closely with the substance injected.^{6,7} Lin et al⁶ demonstrated that paint in a rat model caused significantly more tissue damage than a saline solution at similar pressures. Gutowski et al⁸ described five patients who had high-pressure injection injuries with dry-cleaning solvents that included isoparaffins, methoxypropanolol, and dichloroethane. These substances can have relatively low systemic toxicity but severe local toxicity with tissue necrosis.^{9,10}

High-pressure injection injuries with water or gases, such as air, tend to be significantly less damaging, because these materials have low toxicity. Other substances have also been implicated in high-pressure injection injuries (Box 16-1).

Anatomy affects the degree of spread and injury as well as treatment. The spread of injection depends not only on the pressure of injection and viscosity of material, but also on the resistance of the tissue. For example, the dorsum of the hand provides significantly less resistance to a spreading substance than the palm. Injection over the flexor tendon sheath may result in spread along the flexor tendon sheath and into the hand and forearm. Injection injury to the relatively nondistensible and small space of the finger pulp can result in severe mechanical trauma and ischemia despite limited spread of injection material.

High-pressure injection injuries require prompt treatment to prevent significant morbidity, loss of function, and amputation. The mechanism of injury and the material injected must be identified. Radiographic studies can help delineate the spread of material. Paint, grease, and other agents are radiopaque to varying degrees. The extent of water spread can be determined by the extent of subcutaneous emphysema.

The extremity should be kept elevated, and all patients should receive tetanus prophylaxis and intravenous, broad-spectrum prophylactic antibiotics. The use of systemic steroids may modulate the inflammatory response; however, their use is controversial and is not particularly supported by the existing literature.

Box 16-1 Substances Associated With High-Pressure Injection Injuries

Air	Grease	Oil
Cement	Hydraulic fluid	Paint thinner
Dry-cleaning solvent	Molten metal	Turpentine
Freon	Molten plastic	Water

Fig. 16-1 A, This patient had a left index finger small puncture wound just proximal to the distal interphalangeal joint crease with surrounding induration, loss of sensation, and compromised vascularity of the volar skin distal to the proximal interphalangeal joint crease. B, The wound was explored with a Bruner zigzag incision. The resultant volar defect with exposed tendons is shown after the final wound debridement. C, The volar defect over the left index finger was covered by a superior-based abdominal flap. D, The appearance 3 months postoperatively. (Courtesy of Sanjay Saraf, MD.)

All cases of high-pressure injection injuries, with the possible exception of air, other gases, and water, should be considered surgical emergencies. Wide surgical exploration, debridement, and irrigation with removal of foreign material are essential. A tourniquet may be used, but Es-march exsanguination is discouraged to prevent further proximal dispersion of injected material. Bruner or midlateral incisions can be used for injection injuries to the volar surface of the hand or fingers, and the flexor tendon sheath should be explored¹¹ (Fig. 16-1). Repeat surgical exploration, debridement, and irrigation are frequently necessary. Open wound management may be necessary, followed by delayed closure with good outcomes.¹² Early physical therapy to prevent loss of function is of critical importance, and patients should be advised at the outset of the significant potential loss of function or even amputation. High-pressure injection injuries should be considered a surgical emergency, and any delay in surgical intervention results in poorer outcomes.^{13,14}

INFILTRATION INJURIES

Infiltration injuries are surprisingly common especially in children, with a reported incidence of 11% of all NICU patients^{15,16} (Fig. 16-2). Neonates and infants have small and delicate veins, and unlike older patients, are unable to verbalize pain at an IV site. The smaller the patient, the

Fig. 16-2 IV infiltration injuries with full-thickness skin loss of the distal radial surface.

greater the potential injury from infiltration. Despite these difficulties, most infiltration injuries are preventable. Fastidious nursing care with careful monitoring, automated IV pumps with sensors, and proper dressing and taping significantly reduce infiltration injuries. *Infiltration* and *extravasation* are often used interchangeably. Some authors refer to infiltration as leakage of non-toxic fluid such as normal saline solution, whereas extravasation is reserved for leakage of toxic fluids such as osmotically active agents, ischemia-inducing agents, and chemotherapeutic agents.¹⁷ Other authors have described extravasation as leakage of vesicant agents, which results in blistering and tissue necrosis, and infiltration as leakage of irritants that may cause redness, pain, and inflammation, but rarely tissue necrosis.^{18,19}

Many factors contribute to the morbidity of these injuries, including the site of infiltration, the size of the patient, the amount of fluid leaked into the tissue, the toxicity of the leaked fluid, the general medical condition of the patient, and management. Hospitals have developed and adapted a variety of grading scales that help to effectively communicate the severity of the infiltration and guide treatment.²⁰⁻²²

When these injuries occur in areas with little subcutaneous fat, such as the dorsum of the hand or foot, structures can be exposed, even with minimal tissue loss. The mechanism of tissue damage caused by extravasated agents can be classified as osmotic, ischemic, direct cellular toxicity, and mechanical compression. Secondary infection can also contribute to tissue damage. The agent and its mechanism of tissue damage determine the recommended treatment.

Osmotically Active Agents

Osmotically active agents include hypertonic dextrose solutions, parenteral nutrition solutions, sodium bicarbonate, radiographic contrast dyes, and solutions containing calcium and potassium. These substances can cause tissue damage by creating local osmotic imbalances that can result in cell death by disrupting cell membrane transport or intracellular dehydration. Because solutions containing calcium and potassium are also slightly acidic and hypertonic, they are capable of precipitating proteins, which also results in cell death.²³

Ischemia-Inducing Agents

Ischemia-inducing agents include those with alpha-adrenergic properties, such as epinephrine and dopamine. Certain cations, such as potassium and calcium, may cause ischemia through depolarization and contraction of smooth muscle sphincters. Dopamine is arguably the most common vasoactive drug in extravasation injuries.²⁴ Treatment options used for osmotically active agent extravasation have also been employed for vasoactive agents. Casanova et al²⁴ described using hyaluronidase in an attempt to disperse and dilute the vasoactive agent. Gault²⁵ described a saline flush technique that has been used in cases of dopamine extravasation, but it remains somewhat controversial.²⁵ The best results were obtained when treatment was initiated within 6 hours of extravasation. Other authors have advocated specific antidotes, such as phentolamine and topical nitroglycerin for dopamine extravasations²⁶⁻²⁸ (Fig. 16-3).

Chemotherapeutic Agents

Chemotherapeutic agent extravasation injuries arguably result in the most significant morbidity and can be categorized as vesicants, nonvesicants, or irritants (Box 16-2). Vesicants can be further divided into DNA-binding and DNA-nonbinding (Box 16-3). DNA-binding vesicants bind cellular nucleic acid, resulting in cell death and necrosis. Toxic complexes are released from dead cells and taken up by adjacent, healthy cells, leading to further tissue necrosis and progressive tissue loss over weeks to months.¹⁷ DNA-nonbinding vesicants, including plant alkaloids, are less cellularly toxic with less resulting tissue damage and tend to remain more localized.

Fig. 16-3 A dopamine infiltration injury.

Box 16-2 Chemotherapeutic Agents

Vesicants

Dactinomycin	Mitomycin C
Daunorubicin	Nitrogen mustard
Docetaxel	Paclitaxel
Doxorubicin	Vinblastine
Epirubicin	Vincristine
Idarubicin	

Nonvesicants (irritants)

Bleomycin	Ifosfamide
Caroplatin	Irinotecan
Cisplatin	Melphalan
Cyclophosphamide	Oxaliplatin
Etoposide	Thiopental
5-Fluorouracil	

Box 16-3 Vesicants**DNA-Binding**

Doxorubicin	Bendamustine
Idarubicin	Mechlorethamine
Dactinomycin	

DNA-Nonbinding

Vinorelbine	Docetaxel
Vinblastine	Paclitaxel
Vindesine	

Treatment will depend on the type of chemotherapeutic agent. Dexarazoxane is recommended for anthracycline DNA-binding agents, including daunorubicin, doxorubicin, epirubicin, and idarubicin. Its mechanism of action includes binding iron, preventing the formation of free radicals, and binding and inactivating DNA topoisomerase II; it should be injected within 6 hours and away from the site of extravasation.²⁹ DNA-nonbinding vesicants and irritants can be treated with heat or topical nitroglycerin to promote vasodilation and dispersion of the drug. Hyaluronidase can be used to break down hyaluronic acid, promoting diffusion and absorption of the drug. Other treatment options include infusion of saline solution to dilute the drug, with or without subsequent liposuction techniques to extract the offending drug. If such an approach is considered, it should be done within 6 hours of the extravasation. Sodium thiosulfate has been recommended for mechlorethamine and bendamustine extravasation and is thought to neutralize the formation of free radicals and subsequent tissue necrosis.³⁰

A variety of other antidotes, including vitamin C, heparin fractions, dexamethasone, glucosteroids, alpha-tocopherol, dapson, and dimethyl sulfoxide have been advocated for the treatment of chemotherapeutic extravasations; the possible benefits suggested based on animal studies are unproven in humans.³¹⁻³⁶

In most cases, successful management of infiltration injuries requires careful monitoring and early detection, discontinuation of the infusion, administration of the appropriate antidote, and observation, reserving the possible need for debridement and skin graft or flap coverage for tissue necrosis or evolving lesions.

ENVENOMATIONS

Many species of snake, reptile, arachnid, insect, and sea creature have the ability to deliver noxious substances through bites, stings, or other means for hunting prey and/or for self-defense. Envenomation of humans is almost always defensive in nature. Many of these injuries can be managed expectantly with local measures, but others can be lethal and require emergent intervention and antivenin.

Snakes

Approximately 4000 to 6000 snakebite envenomation injuries occur in the United States annually, resulting in approximately five deaths.^{37,38} Most venomous snakes in the United States include pit vipers and coral snakes, although increasingly, pet enthusiasts are introducing other venomous exotic snakes. Common pit vipers in the United States include rattlesnakes and copperheads.

Most snakebites occur on the lower extremities as a defensive reaction of the snake. Once a snakebite has occurred, the victim should be moved a safe distance from the snake, and any restrictive jewelry and clothing should be removed. If an extremity has been bitten, then it should be immobilized. Tourniquets should not be used, because they can exasperate ischemia and toxin-mediated injury.³⁹ Pressure immobilization can be used in an attempt to limit spread of the venom. Typically, the involved extremity is immobilized with a splint, and an elastic bandage is applied from proximal above the snakebite to distal.⁴⁰ Incision and oral suctioning should not be performed, because it is of no benefit and can introduce oral bacteria into the wound.³⁹ The patient should be kept calm and immobilized and immediately transported to a hospital.

Signs and symptoms of snakebite envenomation range from local pain, swelling, and erythema to systemic manifestations of nausea, vomiting, paresthesias, confusion, muscle tenderness, fasciculations, respiratory paralysis, and death. On arrival at the hospital, patients are evaluated. This includes laboratory studies, and hemodynamic and respiratory support are provided if necessary. The poison control center is contacted, and the appropriate antivenin given if available. Local wound care is performed and a fasciotomy considered if compartment syndrome is evident.

Arachnids

Arachnidae is a class of arthropod that includes spiders, ticks, mites, and scorpions. It includes more than 75,000 species worldwide, 20,000 of which are spiders.⁴¹ Approximately 18,000 species of spiders are venomous. Most cause only local irritation, whereas some are capable of inflicting serious local and systemic damage.

Black Widow

The black widow (genus *Latrodectus*) is probably the most feared spider in the United States. Five species have been found throughout the country, more commonly in the southern states. They are identified by their typical glossy black body and orange hourglass marking on the ventral surface of the abdomen, although only one species carries these specific markings; some carry various markings on their dorsal side. The female spider of this species is typically 1 to 1.5 cm long (three times larger than the male) and is responsible for most bites to humans. Bites usually occur between April and October, because the female hibernates during the winter.

Black widow venom is considered one of the most potent secreted by any animal, and an adult has enough venom to kill a 30-pound child.⁴² The venom contains a neurotoxin, alpha-latrotoxin, that causes massive release of acetylcholine and norepinephrine at the neuromuscular junction, eventually leading to depletion of transmitters and blockage of further signals.⁴³

The bite often causes mild to moderate pain and leaves a wheal and flare. A cramping pain begins at the site of the bite and gradually spreads to the larger muscles, including the abdominal wall. Severe abdominal cramping and pain are the hallmark symptoms of black widow spider bites. Fine muscle fasciculations can sometimes be seen. Nausea, vomiting, weakness, and anxiety are also common. Paralysis and respiratory arrest can occur in children. Severe hypertension is possible.⁴⁴ Treatment includes pain relief with opiates, muscle relaxants, and antivenin if any neuromuscular symptoms are present. Muscle relaxation can be achieved through a variety of measures. Calcium gluconate 10 ml of 10% solution may cause significant pain relief and perhaps is diagnostic, but cardiac monitoring is required with its administration. Valium may also be given in appropriate doses. A horse serum antivenin is available that has a dose of 1 vial for both children and adults, relieving symptoms in 1 to 3 hours, although serum sickness is possible.⁴⁴

Recluse

Recluse spiders (genus *Loxosceles*) are found most commonly in the southern United States, although they are not confined to these areas. Of the 13 species known, the brown recluse (*L. reclusa*) is the most prevalent. It is often called the *violin* or *fiddleback spider* because of the characteristic violin-like marking on the anterodorsal cephalothorax. Of all spider bites, plastic surgeons are most often consulted for that of the brown recluse because of the potential for soft tissue necrosis.

KEY POINTS

- Early recognition and appropriate treatment are paramount for treating injuries secondary to injection, infiltration, and envenomation.
- Improper or delayed treatment may result in loss of function or the need for amputation.
- Knowledge of medical and surgical treatments should be part of the armamentarium of every plastic surgeon to help improve outcomes for these injuries.

Part II

Congenital and Acquired Deformities of the Facial Skeleton and Soft Tissues of the Head and Neck

Psychological Issues Affecting the Treatment of Children and Adolescents With Cleft and Craniofacial Conditions

Kathleen A. Kapp-Simon

Children born with cleft lip and palate (CL/P) and other craniofacial conditions (CFCs) face numerous psychological challenges throughout their lives. This chapter identifies psychological issues that affect adjustment, including differences in family adaptation and child temperament, social skills, and cognitive abilities. Specific issues related to surgical intervention are discussed, along with methods of promoting healthy psychological adjustment in children undergoing treatment for CL/P and other CFCs.

The psychological care of children born with a CL/P and other CFCs is complex and ongoing, beginning at birth and for most children, continuing to young adulthood. This care encompasses issues related to family adaptation, coping with surgeries and other therapeutic interventions, self-esteem, social competence, emotional and behavioral adjustment, cognitive functioning and school achievement, and ultimate integration into society as a fully functioning adult. The plastic-craniofacial surgeon is in a unique position with regard to a number of these issues. The surgeon may be one of the first persons with whom a family speaks who is knowledgeable about the child's condition. In addition, the surgeon has the power to bring about major changes in the child's appearance and functioning. Thus the surgeon's initial presentation about the child's condition and its possible effect on a child's life has the potential for long-term influence. In addition, the surgeon, in conjunction with the cleft-craniofacial team, will see a child and his family

through the many years of habilitation. Consequently, the surgeon will often hear about a child's problems or family concerns in areas beyond his or her expertise.

We will discuss psychological issues as they relate to the clinical care of children with clefts or other CFCs. The initial focus is on the parents and their adjustment to their child's birth. This section is followed by a general discussion of issues related to emotional, behavioral, social, and academic adjustments that affect treatment decisions at various ages in a child's life. Finally, a framework for surgical decision-making during adolescence is proposed.

PARENTAL ADJUSTMENT

Whether diagnosis occurs prenatally or in the delivery room, most parents are unprepared for the news that their child has a CL/P or CFC.¹ Thus they must cope with feelings of shock, loss, grief, and worry as they try to accomplish important tasks that may be as variable as learning to feed their infant, managing their infant's airway, making decisions about immediate treatment priorities, and seeking information about long-term care.² An early referral to both a cleft-craniofacial team and to a local support network or national support program such as The Cleft Palate Foundation (<http://www.cleftline.org>), Ameriface (<http://www.ameriface.org>), or the Children's Craniofacial Association (<http://www.CCAkids.org>), will provide parents with critical information and options for emotional support. There are also online support groups that are specific to the diagnosis. For example, there is an online support group for parents of children with CL/P on Facebook. However, many of these diagnosis-specific groups have short lives; thus referring professionals should be aware that it is not uncommon for websites to be out of date.

Parents are influenced by the attitude that medical professionals display toward their child. While the potential of an individual child can never be known fully at birth, an optimistic presentation of the child's future—with assurances that much can be done to both improve appearance (when appropriate) and foster optimal development—will provide the reassurance that anxious parents need. During clinic interviews with families of older children, the parents have often commented that early encouragement from a medical professional to think of their infant as a “normal baby” enabled them to get past the initial feelings of grief and loss that are so typical.

It is also important to recognize that families who have a child with a CL/P or CFC have personal and family histories that they bring to coping with this new situation. A parent's level of prebirth adaptation and general emotional health as well as the level of family cohesion will influence a parent's ability to cope with the child's birth and will have an impact on long-term family and child adaptation.³ The initial process of adaptation can be challenging, because each parent may have different emotional reactions. One of the parents may be feeling very sad or depressed, whereas the other is angrily searching for someone or something to blame. The degree to which parents are able to validate each other's experiences and coping process will influence the family's long-term adaptation and their child's mental health.

Parental competence is enhanced when parents recognize their differing strengths. One parent may be better equipped to seek out information about available medical/therapeutic treatments, whereas the other parent may do better supporting the young child through surgery. Professionals working with families can recognize and encourage these individual strengths. We do know that when parents believe that they can meet their child's needs, feel satisfaction in their role as parents, and realistically acknowledge the stresses of coping with the issues of raising a child with more complex medical needs, the parent-child relationship can be enhanced in important ways.

Despite the extensive evidence documenting the distress of the initial period following the birth of a child with a chronic medical condition such as CL/P or CFC, most families cope adequately and provide an emotionally healthy environment for their child. However, children are

not only affected by their families but also by societal reactions. There is considerable evidence to suggest that individuals with facial differences must negotiate a plethora of personal challenges to self-esteem and social acceptance after they leave the protective environment of the family.^{4,5} Although most individuals with CL/P or CFC are ultimately successful in coping with these difficulties and mature into productive and contributing members of society,⁶ there can be many sources of stress during the childhood years.

BEHAVIORAL, EMOTIONAL, AND SOCIAL ISSUES

Psychological adjustment in childhood is based on a child's behavioral competencies, emotional adjustment, and social adaptation. Behavior and emotional adjustment encompasses the ability to both internalize and externalize problems. Research has shown that children with CL/P and CFCs are at greater risk of exhibiting personal inhibition, including withdrawal, shyness, separation anxiety, and occasionally depression.⁷⁻¹⁰ There is recent evidence that children 4 to 9 years of age with oral clefts screen positive for separation anxiety disorder significantly more frequently than children without oral clefts (24% screened positive compared with a general population rate of 3% to 5%).¹⁰ However, there are also reports of more frequent acting-out behaviors, which may be age dependent. In one of the only longitudinal studies assessing behavior in children with CL/P, higher rates of acting-out behaviors were identified for boys at 6 and 7 years of age, which decreased over time. Girls also displayed acting-out behaviors, but not until 11 to 12 years of age. Internalizing problems was higher than the norms for both sexes; however, inhibition increased for girls as they got older, whereas it remained fairly constant for boys.¹¹

Issues related to self-concept have been intuitively linked to facial appearance, with parents, surgeons, and other team professionals assuming that improved facial appearance results in more positive global self-perception by the child or adolescent and greater social acceptability from peers. As with many commonly held perceptions, there seems to be some truth to this linkage. Children frequently blame social difficulties on facial differences.^{12,13} Peer teasing and victimization of children with CFC are often attributed to the presence of facial disfigurement.⁵ Recent quality-of-life research has found that even adolescents perceive that they are teased and made to feel unwelcome by peers frequently and that facial appearance has a strong influence on social relationships.¹⁴ Teasing from peers is not a benign experience for children. Peer teasing is associated with poorer psychological functioning, including increased symptoms of depression, anxiety, behavior problems, and dissatisfaction with appearance.^{15,16} Children seen in cleft and craniofacial clinics should be routinely screened to assess the frequency and type of peer teasing that they are experiencing. Schoolwide interventions are often needed to counter the negative environment that permits peer teasing at school.¹⁷

In addition, children with facial differences will benefit from being taught strategies to enhance their ability to interact appropriately with their peers. Social skills are specific positive behaviors that can enhance social interaction. Children with better social skills are reported to have fewer behavior or emotional problems and are less likely to be socially inhibited or withdrawn.^{18,19} Social skills, such as making eye contact, maintaining appropriate social distance, entering and maintaining conversations, managing social anxiety, and expressing empathy are all skills that can be taught.²⁰ Preliminary research findings indicate that children who are taught specific social skills can significantly increase the frequency with which they initiate contact with their peers and the frequency with which these contacts lead to more social interaction.²¹ Recently, the Center for Appearance Research in Bristol, United Kingdom, has launched research evaluating an on-line program for individuals with facial differences that incorporates current knowledge about social interaction, social anxiety, and cognitive behavioral interventions into a seven-session on-line teaching program: www.yfaceit.co.uk.²² A similar program for adults has been successful in decreasing anxiety and depression and increasing positive adjustment.²³

COGNITIVE FUNCTIONING

There is considerable research to support a higher risk of learning disorders in children with CL/P and other CFCs.²⁴ Thirty percent of children with CL/P (compared with 5% to 15% of the general population) experience specific reading disabilities,²⁵ and children with other types of CFC may experience learning problems resulting from hearing loss, reading disabilities, problems with attention, or nonverbal learning disabilities.²⁶ Children with CL/P access special education services at a more frequent rate.²⁷ Population-based studies suggest that as a group, children with CL/P lag behind their peers in most academic areas, even though individuals with CL/P may be very successful.²⁸⁻³⁰ There is growing evidence of a neurobiologic basis for at least some of the learning challenges that many children with CL/P experience. The research by Nopoulos and colleagues³¹⁻³⁷ has identified numerous changes in brain morphology and shape that are associated with cognitive functioning and specific aspects of academic achievement in individuals with CL/P. These authors have repeatedly asserted that individuals with CL/P are at risk for having a neurodevelopmental disorder that has an impact on both learning and social behavior.³⁸

Learning problems become most evident during the early elementary school years, particularly as demands for reading competency emerge. Consequently, a significant proportion of the young children seen by cleft and craniofacial teams are coping with multiple risks to adjustment at a very young age. Integration into the peer group is often more difficult for children who have learning problems, especially if they also have facial differences and behavior problems. Learning problems can add to a child's feeling of lowered self-confidence.

School districts do not always recognize that a child with CL/P or CFC has a specific learning disability. A child who is inhibited and has the stigma of a facial difference may be viewed as less intelligent by a teacher, and the true processing deficits that account for the child's learning difficulties may not be identified.³⁹ At the other extreme, a child who acts out in the presence of learning problems and social difficulties may be diagnosed with an attention deficit disorder, and the underlying learning disorder may not be properly identified or treated.⁴⁰ Current practices to screen academic progress for all children on a regular basis as part of the new educational initiative called Response to Intervention (RtI) has increased the probability that children will be receiving some interventions at an earlier age; however, it has also meant that children who are struggling may not receive appropriate diagnostic assessments that would identify learning disabilities in a timely fashion. As a consequence, the required intensity of early intervention may be delayed unnecessarily.

Cleft teams are in a unique position to educate families about the possibility of learning disorders in their children. Neurodevelopmental screenings should be provided, beginning in infancy. Children identified at risk should be referred for early intervention services. Preschool screening should include an assessment of phonological awareness, because weakness in this area is an early indicator of potential learning challenges. Academic progress should be evaluated during the early elementary school years, ideally by the cleft or craniofacial team. Children who are not keeping up academically with peers should be evaluated for specific learning disabilities. If resources are not available within the cleft team, parents should be instructed in their legal rights to an assessment through their school district (see <http://idea.ed.gov/> for further information on special education rights), or they should be referred to the psychology departments of a major medical center or university for evaluation.

TREATMENT ISSUES

Cleft Lip and Palate

The basic goals of CL/P treatment are quite straightforward: (1) to provide surgical closure of the lip while achieving the best possible appearance and function of the lip and nose, and (2) to close the cleft of the palate well enough and early enough to allow normal speech articulation and airflow while minimizing negative effects on tooth development and facial growth. However, in reality, achieving these simple goals can be complex. Parents of children with CL/P often feel confusion about the different treatment approaches that are advocated. With increased communication among parents because of Internet access and other sources of support organizations, the parents of an infant with CL/P may quickly realize that there are many different approaches to the treatment of their child's CL/P. They learn about feeding appliances, nasal molding appliances, active and passive presurgical appliances, early versus late bone grafting, and so on.

Parents may feel that they need to become “experts” at cleft surgery so that they are able to make informed choices. They worry that they will make the wrong choice and their child will suffer irreparable damage. Consequently, it is critical that parents be given the message that there are many valid and acceptable ways to address the surgical treatment of their child. Honest acknowledgment of the different approaches, including recognition that other approaches can be successful, while expressing confidence in the approach that your team uses, will reassure the family. Parents can be counseled that “We are confident in the approach we take in our team; however, other teams may take a different approach and still obtain very good surgical results. There are many paths that lead to a similar outcome.” Justification for your approach, with good outcome data, will ease parental anxiety and help them make an informed choice.

Craniofacial Conditions

The timing and frequency of surgical intervention is an important issue that affects surgical care across diagnostic categories. The surgical needs of children with CFCs are often very complex, and it is not uncommon for some children with craniofacial syndromes to have 20 to 30 surgeries during childhood. In these situations it is often difficult to balance the child's emotional needs with treatment objectives. Each time a child is hospitalized, regardless of the length of the hospitalization or seriousness of the procedure, the child and family must cope with a variety of stressors. The general rule is that the fewer surgeries a child must experience, the better for the emotional development of the child and family.

General Considerations

Children react in diverse ways to the recommendation for surgery. Even if the child desires improvement in appearance or functioning, the idea of blood tests, intravenous lines, and anesthesia is stressful and may add tension to the parent-child relationship. Surgery also interrupts a child's social life, including peer relationships, school activities, and athletics. For some parents a recommendation for surgery may bring back all the emotions associated with the child's birth, regenerating feelings of sadness, anxiety, and guilt. In addition to these stresses, parents must also cope with time off work, care of their other children, financial worries, insurance hassles, and the logistics of transportation and lodging during the child's hospital stay. Consequently, it is critical that families play an active role in determining the focus and timing of surgeries.

Surgeries for CL/P and CFC are generally recommended in stages across childhood. There are some surgeries that are time specific, such as a craniotomy, secondary management of the palate to improve speech, a bone graft timed to coincide with tooth development, or midface

advancement. However, many of the procedures, while clearly medically indicated, can be done when the child and parents are ready. Factors to be considered when discussing these types of time-elective surgeries include the child's age, temperament, psychological adjustment, motivation, and expectations, and the parents' ability to encourage and support their child.

There are individual differences in children that are developmental, physiologic, and temperamental.⁴¹ Both genes and environment influence these individual differences. Physiologically, some children may react to stress with a markedly increased heart rate or by vomiting, whereas other children will react to the same situation with less intensity. The intensity of the physiologic reaction has a biologic basis and is less under the control of the child. Children also differ on temperamental dimensions, such as vigor of motor activity, tolerance for frustration, quality of mood, attention span, and degree of inhibition. Both physiologic and temperamental characteristics have a biologic basis; in addition, the reactions of parents and other adults to the child's behavioral responses when under stress also contribute an environmental stimulus that may influence the child's long-term adjustment.³

Three broad personality types that have their basis in physiologic reactivity, temperament, and behavior and that have been reliably replicated for large groups of children have been identified by child development researchers.⁴² These personality types can be described as the *resilient*, *overcontrolled*, and *undercontrolled child*. The resilient child is defined as socially facile with adults and children, lacking in shyness, and possessing positive emotions. A child who fits the overcontrolled type personality is extremely shy, somewhat anxious, compliant, and dependent. At the other extreme, the undercontrolled child is uncooperative, more likely to be impulsive and non-compliant, displays predominantly negative emotions, and has social problems with peers. These personality types are present on a continuum, so these characteristics can be more or less defining for an individual child. The child's innate personality will influence the way he or she will behave, think, and feel in many situations and thus may shape the surgical experience.

Two- to Five-Year-Old Children

A younger child can successfully undergo a lip revision if the preschooler is calm and cooperative (characteristics of the resilient child) and the child's parents are able to provide emotional support and behavioral guidance. An energetic, active toddler or preschooler who is always on the go (even if otherwise similar in personality to the resilient child) is more likely to accidentally injure the surgical site through a fall or some other mishap during the recovery period and is probably not a good candidate for lip revision at a young age regardless of parenting skill.

A toddler or preschooler who is extremely shy and thus uncooperative during the clinic evaluations (overcontrolled) would probably also benefit from waiting until an older age for elective revisions. An overcontrolled preschooler is more likely to experience excessive anxiety and stress related to the various aspects of hospitalization and surgical care. Younger children do not have the cognitive abilities to actively participate in decision-making regarding a procedure, nor do they have the psychological skills to cope effectively with the stress of surgery, but they do understand that things are being done to them that they do not like. If the parents of a child who fits the description of the overcontrolled child are themselves anxious and dependent, they will have difficulty providing adequate support for their child. However, parents who are warm, encouraging, and patient with an anxious child may be able to provide an environment that will allow their child to successfully tolerate a surgery at a younger age. Thus individual decision-making is the key when working with a child who fits the overcontrolled personality type.

There are some preschoolers who are truly difficult to manage. These children may have been more irritable as infants, and may have a lower tolerance for stimulation, a high activity level, and intense reactions to new people and environments (the undercontrolled child). In general, an undercontrolled child is not a good candidate for elective surgery during the toddler or

preschool years. If a surgery must be performed on a young child who fits the undercontrolled personality type, both parents and hospital staff should be prepared for the possibility of strong reactions from the child. An undercontrolled child is more likely to pull out an IV line, injure a surgical site, or refuse to eat or drink after surgery. To counter these behaviors, presurgical planning and parent counseling may be indicated; however, even under the best of circumstances, it will be difficult to support an undercontrolled child through surgery at a young age.

If a toddler or preschooler is to undergo surgery, special support will be needed to make the surgical experience as stress free as possible. Parental involvement can be very beneficial, particularly when parents recognize the temperamental characteristics of their own child and are able to support the child appropriately when the child is stressed. Parents can be taught to distract their child in a positive way during potentially stressful procedures such as blood drawing or wound cleaning. Parents should be encouraged to cuddle and reassure their child through simple words that communicate confidence (such as “You’re doing well,” “Mommy’s here with you,” “Let’s read, sing, play,” and similar messages). Parents and professionals all need to recognize that young children express distress and fear through crying, resistance, and withdrawal. Hospitals are frightening places, and many children will be distressed during a hospitalization. Parents and surgeons can help children cope more effectively with the stress of a hospitalization if they acknowledge children’s fears as valid while simultaneously providing the emotional support they need. Young children especially benefit from opportunities to use play to express fears, and hospital-based therapists (such as pediatric psychologists or child-life therapists) can be consulted for help in this area.⁴³

School-Aged Child

A child’s entrance into elementary school is a major milestone. Families and surgeons share the goal of having a child look as normal as possible when that child begins formal education in the hope that a more normal appearance will increase the child’s positive social reception and minimize negative attention and teasing from peers. Certainly every child deserves to look as good as possible as they approach elementary school age. When a child enters first grade, they will find themselves rubbing shoulders with children of various ages, many of whom will be more aware of differences in appearance than the child’s preschool classmates have been. Consequently, the potential for teasing, bullying, and social exclusion becomes greater. However, teasing and negative social contacts are not just due to appearance issues. There have now been several studies that found children with CL/P to be more inhibited and more anxious, more socially isolated, and less friendly to peers than unaffected children.^{9,12,44} Murray et al⁹ reported that the primary correlate of these social difficulties at age 7 was the child’s ability to communicate effectively, including both articulation and the pragmatic aspects of communication (eye contact, tone, and volume of voice) and not the child’s appearance. Thus it is critical that improvement in appearance be presented as only one factor affecting social acceptance for the school-aged child.

Certainly we want children with facial differences to have the benefit of the best possible appearance; however, we do families a disservice if we encourage them to think that improved appearance will cure their child’s social difficulties or prevent peer teasing. Most children are teased at some time in childhood, and many children with facial differences do not experience teasing about their faces.¹⁶ Even children with facial differences who are being teased are not always being teased about their face. The causes of the social difficulties are multifaceted; therefore it may be better to present the timing of surgical revisions as occurring in the context of physical and psychological maturation rather than relate them to school entrance or prevention of social problems. Parents are rightly concerned about the possibility of teasing when appearance is deviant; however, whenever surgical revisions are discussed in response to concerns about teasing, members of the cleft-craniofacial team should take the time to talk about the prosocial skills that

children with appearance differences can use to minimize negative social interactions. For example, parents could be encouraged to consider how their child approaches peers and how the child responds to the social approaches of others. These discussions need to be framed so that the child is not “blamed” for teasing that occurs. The focus can be on broad factors that influence social acceptance for children, particularly social interaction skills that promote friendship, such as making eye contact, speaking with appropriate volume, greeting peers in a warm and gracious manner, responding appropriately to the initiation of peers, and knowing how to bring up topics of conversation that are of interest to peers.^{4,12,21} As previously mentioned, parents should also be encouraged to speak with school personnel to ensure that they have programs in place to prevent school bullying.¹⁷

Personality types continue to play a role as children enter elementary school. Professionals often wonder why a child with minimal scarring or facial deviance experiences excessive teasing, while another child whose scarring or deformity is much more severe is not reporting difficulties. The latter child most likely fits into the resilient personality type. That child is more likely to have a friendly approach to peers, to know how to share and give compliments, and to have a generally positive mood. When questioned about facial differences, a child with a resilient personality type is not likely to take offense, but will answer questions directly, with dignity and confidence. For children who fit the resilient personality type, surgical revisions tend to be viewed as a way to improve appearance, not as a way to make more friends or prevent teasing.

Children who are overcontrolled are most often viewed as “very well-behaved children” in school. They are quiet and may also be very conscientious. Unless a child who is overcontrolled also has learning disabilities, school achievement is likely to be good. However, children who are overcontrolled are also more likely to withdraw from social contacts. They may regularly choose to play alone, put their head down and refuse to speak when another child addresses them, and may display other signs of anxiety. This type of child is quite vulnerable to taunting from peers. Children who are overcontrolled may benefit from direct teaching of social skills to help them overcome the extreme shyness exhibited. Improving the appearance of a child’s face without also addressing the social inhibition issue is unlikely to affect the patterns of social interaction that have developed in the peer group.

A child who fits the undercontrolled personality type is at higher risk for global behavior disorders in general and externalizing disorders in particular during the school years.⁴² Even if the child does not have a specific learning disability, the undercontrolled child is more likely to have achievement problems that are related to behavioral issues (attention, motivation, and/or compliance) and is at greater risk for being openly rejected by peers because of the tendency toward aggression, difficulty learning to share or focus on another’s needs, and negative emotions. The presence of facial differences may become the focal point of “blame” for the child’s behavioral and social difficulties, and some families may hope that an improved appearance will have a positive effect on the child’s adjustment. Experience suggests that these families are generally disappointed unless direct action is also taken to address the underlying behavioral issues that are the primary source of the child’s problem. In this type of situation, a referral for a psychological consultation to determine an appropriate psychotherapeutic intervention is critical. Often the combination of psychological and surgical intervention can make a significant difference in the child’s overall adjustment.

Adolescents

Adolescence is a time of turbulence for many youths. Issues of identity, independence, and sociability are the major tasks of this age group. Relationships with adults and parents are redefined

as the adolescent seeks to establish a sense of self that is separate from the family of origin. The values of friends are compared with those of family members and sometimes chosen over those taught within the home. An individual's perception of personal success or failure may depend on his or her status in the social group.⁴⁵

Issues related to objective differences in facial appearance complicate the already complex tasks of adolescence for teens with CL/P or CFC. Teens must decide whether they will allow the presence of facial differences to interfere with social relationships, including dating relationships, during the high school years. Self-consciousness regarding appearance is normative during adolescence; however, when a teen has visible facial differences, the level of self-consciousness may intensify. Surgery may be desired to achieve the positive differences that are anticipated; in contrast, surgery may be feared because of the additional attention it will bring to the teen. Surgery may also interfere with activities that teens enjoy, such as sports, playing a horn or reed instrument, and summer jobs. Decisions regarding surgery create additional tension for teens. There may be disagreements between the teen, parent, and surgeon about surgical priorities or even whether additional surgery should be performed.

Few studies have objectively examined the rate of agreement between parents and adolescents regarding the importance of elective procedures to improve appearance. However, in a well-designed study, Turner et al⁴⁶ essentially found no agreement between parents and their 15-year-olds regarding satisfaction with cleft-related facial features. Based on paired comparison, parents expressed significantly greater overall satisfaction than the adolescents regarding the outcome in cleft-related areas. If parents and teens view treatment outcomes differently, who should control the decision-making process regarding additional elective treatment during adolescence?

Strategies are available to help parents and adolescents resolve differing views about the end-point of cleft-craniofacial care. The "Self-Understanding Model" provides a structure for helping families articulate differences of opinion regarding additional treatment.^{20,45} Using this model, both teens and parents are able to identify their own motivations for having or not having additional surgical treatment. Disagreements between parents and teens frequently occur because of misperceptions of motivation and false attribution of the meaning of additional surgery to the family. Open communication, encouraged and guided by members of the treatment team, can help families determine treatment priorities. This type of direct communication may help preserve the self-esteem of the adolescent and ensure that planned surgeries are being performed with the teen's cooperation. Research also suggests that active participation in decision-making by the teen results in increased satisfaction with the surgical outcome.⁴⁷

CONCLUSION

The treatment of CL/P and CFC extends over the infancy, childhood, and adolescence of individuals who are born with this condition. The children and their families contend with multiple surgeries throughout these years. Depending on the nature and severity of the condition, the families may also need to cope with ear infections, hearing loss, feeding tubes, speech therapy, learning disabilities, behavior problems, and various orthodontic treatments. The end result of these treatments and interventions should be a child, teen, and adult who is medically and psychologically healthy and an appropriately contributing member of society at each stage of development.³ The psychological support needed to enable a child to meet that goal should be provided by the family, surgeon, psychologist, school, and other members of the cleft treatment team. These adults should demonstrate a belief in the child's ability to cope with the challenges of medical treatment related to the CL/P or CFC and should focus the child on the efficacy he or she will gain from having had the experience of growing up with a CL/P or CFC.

KEY POINTS

- Medical professionals can influence the expectations of parents who have newborn infants with facial differences.
- Children should participate in the surgical decision-making process as appropriate to their developmental age.
- A young child's ability to cooperate with surgery is influenced by innate temperament, hospital environment and support, and the family's parenting skills.
- Developmental, physiologic, and temperamental differences in children affect their ability to cope with recommended medical treatments.
- Children with facial differences can be taught positive social interaction skills that encourage positive peer relationships and promote psychological adjustment.
- Children with CL/P and other CFCs are at higher risk for specific learning difficulties, which can be overlooked by teachers.
- There is growing evidence that learning disabilities in children with CL/P and other CFCs have a neurobiologic basis.

Craniofacial Syndromes: Genetics, Embryology, and Clinical Relevance

Adel Y. Fattah

Understanding Genetics and the Basis of Development

The development of the craniofacial complex is fascinating for its convergence of multiple interacting systems in a small space. This chapter is divided into two sections: the first section will outline the basics of genetics for surgeons and introduce the principles of development pertinent to congenital malformations of the head and neck. The second section will provide an overview of craniofacial development by region, relating the developmental processes to the clinical conditions to foster a deeper understanding.

Molecular Biology's Influence on Gene Function

The power of molecular biology techniques and the science of experimental embryology unified to create the discipline of developmental biology. This technologic advancement has allowed scientists to alter specific genes, insert them into model organisms, and evaluate the changes they produce during embryogenesis. This has led to the publication of a significant number of papers describing anomalies in experimental animals that are analogous to human conditions. This in turn has helped direct clinical geneticists searching for candidate gene mutations when faced with an unknown craniofacial anomaly.

Box 18-1 Definitions

Congenital A feature existing at birth

Anomaly Any abnormality from the normal situation

Syndrome A collection of anomalies occurring in two or more embryologically distinct areas

Sequence A pattern of multiple anomalies presumed to be caused by a single factor

Malformation A morphologic defect resulting from a faulty developmental process

Disruption A morphologic defect caused by interference with a normal developmental process

Deformation A morphologic defect caused by a nondisruptive mechanical process

Dysplasia Abnormal development

Dysostosis Abnormal bone development

Familial Clustering of a particular feature in a family more than would be predicted by chance alone

Sporadic Any disorder occurring without a family history

Penetrance The proportion of individuals carrying a gene that displays an associated phenotype; if some do not exhibit signs and symptoms of the genetic disorder, it is said to have incomplete penetrance

Variable expressivity Variation of a phenotype within the same genetic disorder

Gene expression The manufacture of mRNA, which is then translated into the protein product by ribosomes

Molecular analysis is generally evaluated by the geneticist on the craniofacial team and is typically of limited interest to the surgeon, apart from confirming a diagnosis and knowing the impact that the diagnosis will have on the natural history of the child before and after surgery. However, genetic literacy will be important as we enter an age of molecular medicine, and doctors will require a working knowledge of the techniques and limitations of genetic testing. Furthermore, acquaintance with a few basic principles will allow a deeper understanding of the conditions we treat and empower surgeons to better conceptualize the pathologic basis of the anomaly. Some basic definitions are given in Box 18-1.

Gene Naming Conventions and Why the Names Are Often Strange

Many genes are named for what goes wrong when the gene does not work. Others are named for the protein for which they code, such as a fibroblast growth factor receptor. Many genes were initially identified in the fruit fly (*Drosophila*), with homologs identified in vertebrates: typically there is more than one version, which by evolution are co-opted for different functions. The fruit fly name for the gene is usually slightly modified for the vertebrate homolog. For example, a gene that causes the fruit fly larvae to have a prickly surface is called *hedgehog*. Three versions of hedgehog are found in vertebrates: *Sonic hedgehog* (SHH, a key patterning gene in multiple developmental processes), *Indian hedgehog* (involved in bone growth and fracture healing), and *Desert hedgehog* (loss of this leads to infertility). This history explains why many genes have seemingly unfathomable names. Such names are typically shortened to an initialism, with italicization and capitalization used to denote the species and whether one is referring to the DNA/RNA or the protein. Italicized gene names refer to the DNA or RNA; the nonitalicized version refers to the protein product. With some exceptions, using all capitals refers to the human species. If the first letter is capitalized, it refers to the mouse. If it is all lower case, then it refers to *Drosophila*, chick, frog (*Xenopus*), and zebrafish (*Danio*), which are the main model organisms. For example, SHH: human Sonic hedgehog protein; *Fgfr3*: mouse fibroblast growth factor receptor-3 DNA/RNA.

Box 18-2 Morphogenetic Mechanisms

- Cell division
- Cell differentiation
- Interaction of cells with extracellular matrix (for example, cell migration, branching of lung buds, invagination of otic placode)
- Induction: The effect of one tissue upon another signaling (for example, epithelial-mesenchymal interactions [tooth germ induction])
- Apoptosis

IMPORTANT CONCEPTS**Regional and Local Signaling Networks**

The morphology of the organism is created in a stepwise fashion after fertilization. The initial specifications of a body plan are given (for example, specifying cranial from caudal, left from right, dorsal from ventral). Thereafter, a cascade of signaling networks is set in motion to fashion the various parts of the organism; such regional signaling systems give way to local signals that are responsible for refining the pattern of the organism. For example, cell signaling positions the limb along the body axis, and then it patterns the limb, then the digits, and then the morphology of the skeletal elements within the digit.

As a consequence of this sequence, cells switch from a *pluripotent* (“stem cell–like”) situation to a commitment to the tissue to which the cells will contribute. How this is achieved is a function of their gene expression and is still only partially understood. Although signaling networks establish a body plan and the basic structures of the embryo, morphogenesis ultimately creates the form and shape of the organism and is distinct from cellular differentiation. Morphogenesis has a physical and mechanical basis, and current concepts in development are founded on the principle that differential gene expression leads to cellular interactions that create differences in morphology. Some mechanisms responsible for shaping the embryo are listed in Box 18-2.

Genes Make Proteins—Not Body Parts or Syndromes

Genotype refers to the genetic composition of an organism, whereas *phenotype* refers to the observable characteristics, which include morphology (that is, clinical signs), physiologic changes, and even behavior. The phenotype is in part dependent on the genotype, but also on environmental factors; as a consequence, the same genotype may result in different phenotypes (such as in identical twins raised in different environments).

Genes are transcribed into messenger RNA (*mRNA*), which is translated by ribosomes into amino acid chains that are assembled into proteins. The same genes and signaling pathways are used in many seemingly unrelated processes; for example, *SHH* is involved in many processes, including specifying the anteroposterior (radial-ulnar) axis of the limb, neural induction, and cholesterol metabolism. Therefore one of the most important concepts to grasp is what a gene does; a gene does not “make” an organ. If we remove *Pax6* from the genome, the eyes do not form.¹ However, *Pax6* does not code for an eye; it makes a transcriptional regulator that activates and represses a number of genes downstream that set in motion signaling processes and cellular interactions that culminate in eye formation.

Box 18-3 Nomenclature for Chromosomal Abnormalities (Paris Nomenclature)

p	Short arm (petit)
q	Long arm
13q32	Long arm of chromosome 13 (32 refers to the region of the chromosome)
del, D or Δ 22q11	Deletion of region 11 on the long arm of chromosome 22
t(3;13)	Translocation from chromosomes 3 to 13
t(3;13)(p21;q3)	Above translocation with the breakpoints specified

There Is No Gene for Apert Syndrome

By extension, there is no such thing as a gene for a specific syndrome, such as a gene for Apert syndrome. The gene mutated in Apert syndrome is a receptor for fibroblast growth factor (*FGFR2*) that transduces the FGF signal into the cell and initiates a cascade of intracellular processes. In Apert syndrome, this mutation accelerates endochondral ossification.² However, a different mutation in the same gene leads to reduced chondrocyte proliferation and a distinct syndrome called *Crouzon syndrome*.³ Environmental factors (for example, raised intracranial pressure) then act on this genotype to create the phenotype that is evaluated in the clinic.

The point is that genes do not code for syndromes; a syndrome refers to the constellation of features seen clinically. This apparent conflict arises from physicians and scientists trying to classify things from opposing perspectives. To a physician, a syndrome is a collection of clinical signs that may be caused by multiple different gene mutations; to a scientist, mutations in a gene may cause multiple different syndromes. At this point in our knowledge, there is no unifying classification; therefore syndromes and gene mutations will sometimes coincide, but sometimes they will not. It has been suggested that most patients can be assigned three diagnostic terms: phenotypic, pathologic, and genetic.⁴ For example, *plagiocephaly* is a phenotypic description, *unicoronal synostosis* is a pathologic diagnosis, and *FGFR3*^{P250R*} (Box 18-3) is a genetic description of the same condition.

Multiple Genes Have Overlapping Functions: Redundancy

Many important components in signaling, metabolic, and developmental pathways have multiple similar genes that appear to be functionally redundant. This is thought to be a consequence of genes being duplicated over evolutionary time. When one gene is inactivated, another is able to compensate as a result of the overlapping function. In humans, *Alx3* loss-of-function causes a midline facial anomaly called *frontorhinia*.⁵ By contrast, *Alx3* knockout mice have no anomalies, yet a double knockout of *Alx3* and *Alx4* creates a “split-face” phenotype. This example demonstrates functional redundancy (*Alx4* can compensate for the loss of *Alx3*), and furthermore, that the phenotype may differ between species and genetic backgrounds, as discussed later. Why we should have two genes when one will suffice has been a topic of debate. It has been suggested that this is a “belt and braces” fail-safe mechanism, or a process that modulates cell signaling.⁶

*The *P250R* informs the reader of where the mutation is. In this instance, a **P**roline is replaced with an **aR**ginine residue at the 250th position in the amino acid chain. Similar notation can be used for the DNA sequence; in this case, it is c.749C>G.

Relationship Between Genes and the Environment

Genes are not independent of their environment; some genetic effects are seen under certain environmental conditions, or the response to an environment may depend on the genotype. Genes are influenced by their environment in a number of ways; for example, ionizing radiation exerts its effect by directly breaking one or both strands of a DNA molecule, creating *de novo* mutations. By contrast, *epigenetic factors* are those that influence gene expression without altering the DNA. Epigenetic factors may be exogenous compounds or even chronic disease states that lead the body to produce certain factors that influence gene expression. How epigenetic factors affect gene regulation is an area of active research, but we know that they may affect any stage of the DNA-to-protein process and are a source of variation between normal individuals.

It is easy to forget that genes act within the environment of the cell, surrounded by a multitude of other gene products that can modify their behavior (the genetic background). Transcription factors are proteins that bind to the DNA and read the code, expressing it as an mRNA that will go on to make a protein. These factors may be sensitive to chemical signals that may be released in response to external stimuli, such as hormones and neurotransmitters that may alter gene expression. Such agents that disrupt normal development are called *teratogens*. Retinoic acid (vitamin A; Accutane) is involved in normal development, but high exogenous concentrations will cause a very specific pattern of anomalies in the fetus, dramatically reducing the first and second branchial arches. It appears to do this through its effect on *Hox* genes, limiting cranial neural crest proliferation and migration.^{7,8}

COMMON EXPERIMENTAL TECHNIQUES REFERRED TO IN THE LITERATURE

Understanding the function of a gene *in vivo* may be studied in essentially three ways: increasing the expression of a gene, reducing or removing its expression, or expressing the gene in a different place or time from the normal situation. In these instances, the sequence of the gene must be known before it can be manipulated and its function studied, an approach called *reverse genetics*.

Knockout and Knockin

Conventional (first-generation) *knockout mice* are created by a process whereby a gene of interest is replaced with nonfunctioning DNA. All cells in the embryo possess this defect, so if the gene in question is important for early development, embryonic lethality precludes study at later stages. By contrast, *conditional knockout mice* allow investigators to activate and deactivate genes in specific tissues or at specific times; this is called *targeted mutagenesis*. Similarly, *knockin* of gene function allows one to introduce a gene where or when it is not normally expressed and evaluate the outcome on development; this has allowed more focused studies of gene function.

Knockdown

Knockdown refers to a transient inactivation of gene function, which can be achieved by a variety of processes. A short sequence of nucleic acid (oligonucleotide; “oligo”) can bind to the gene and block transcription, bind to mRNA to degrade it (small interfering RNA [siRNA]), or block its translation into protein. This method allows one to switch genes off at specific times to elucidate function during specific developmental processes and may be used *in vitro* as well as in a number of animal models, especially zebrafish.

Gene Overexpression

Transgenic technology in species other than mice is limited, so overexpression of a gene has been produced by numerous other methods, including *retroviral overexpression*, which has been superseded by *electroporation*.⁹ Use of animal models such as the chick and zebrafish allows scientists to surgically manipulate the embryo as well as control gene expression, which is a powerful combination of techniques.

CLINICAL GENETIC TESTING: WHICH TEST FOR WHAT PROBLEM?

We will outline the basics of testing to arm the surgeon with sufficient information to converse with clinical geneticists and prepare for the new technologies that are on the horizon.

Genetic testing looks for differences between the genome of an affected individual and that of the normal population. These differences may be microscopically visible (for example, trisomy or large deletions), or they may be variations in the amount of a region of the genome that is not visible: *copy number variation* (CNV). Most humans have approximately 100 CNVs in their genome, and they are largely innocuous. *Single nucleotide polymorphisms* (SNPs) are changes to a single base of the DNA; every individual has about 3 million SNPs. Some are specific mutations that cause a genetic disorder, and some may predispose to disease, but most are benign. The complexity of genetic testing arises from differentiating normal genetic variation from disease-causing mutations.

Three general categories of testing exist:

1. *Cytogenetic*: Looks for chromosomal abnormalities
2. *Biochemical*: Analyzes proteins typically for inborn errors of metabolism
3. *Molecular*: Examines DNA sequences

Cytogenetic Testing: Karyotyping

Cytogenetic tests evaluate whole chromosomes for changes in number and structure and is the first tier of testing in a number of clinical situations. Perhaps the oldest technique still widely used, *karyotyping*, is the examination of chromosomes under a light microscope. The cells are lysed and fixed on a microscope slide and labeled with Giemsa stain to create the banding (G-banding) pattern that is characteristic of each chromosome, permitting identification. There is a standardized numeric system for these bands, and by looking at the banding pattern and comparing that with a normal karyotype, absence, duplication, and translocation of large portions of the genome (whole chromosomes, such as trisomy 21 or parts thereof) can be detected. These chunks of the genome are large and may span many specific genes as well as the intervening portions (*introns*).

Molecular Testing

In Situ Hybridization

Hybridization is the annealing (joining) of two complementary copies of DNA and the basis of virtually all molecular techniques. If one of these is labeled, for example, with fluorescence, this is called a *probe*, and one may visualize where these sequences are in tissues (in situ). *In situ hybridization* (ISH) is used to look at the presence of specific DNA or RNA sequences in different situations. To use this method, one needs to know the base sequence of what is being sought to synthesize the probe^{10,11} (Fig. 18-1).

Fig. 18-1 In situ hybridization. **A**, Wholemount in situ hybridization of the forelimb with a probe to *Gdf5*¹ labeling the perichondrium and interphalangeal joints (*black arrow*). **B**, Light field view of embryonic heart. **C**, Radiolabeled in situ hybridization of the heart with probe for *frzbl*² labeling the neural crest derived cardiac outflow tract (*white arrow*). (*at*, Atrium; *mc*, myocardium; *oft*, outflow tract.)

Fluorescent In Situ Hybridization

Fluorescent in situ hybridization (FISH) is the most common form of ISH in clinical practice, whereby fluorescent probes are hybridized to a karyotype specimen. FISH is relatively sensitive, specific, and rapid. The label is observed under a fluorescent microscope and pinpoints where on the chromosome the complementary DNA sequence in question may be found. This can then be reported by standard cytogenetic nomenclature (for example, $\Delta 1q36$; Table 18-1). FISH cannot serve as a screening test; the clinician must be looking for a specific known genetic anomaly that can be confirmed or refuted by FISH. Therefore FISH is used to confirm a suspected clinical diagnosis, such as 22q deletion sequence, by the absence of fluorescence (it is deleted).

Comparative Genomic Hybridization or Chromosomal Microarray Analysis

Comparative genomic hybridization (CGH) or *chromosomal microarray analysis* (CMA) is another molecular method for analyzing gains and losses of DNA that are not detectable with routine karyotyping or FISH. The chromosomes are fragmented and arranged in a grid pattern so that each fragment can be identified; the relative degree of fluorescence relative to control DNA is analyzed. Differences in this are regions of genomic imbalance; it does not detect changes such

Table 18-1 Amino Acid Nomenclature

Symbol	Amino Acid	Symbol	Amino Acid
A	Alanine	L	Leucine
R	ARginine	K	Lysine
N	AsparagiNe (Asn)	M	Methionine
D	aspartic aciD (Asp)	F	Fenylalanine
C	Cysteine	P	Proline
E	Glutamic Acid (Glu)	S	Serine
Q	Qlutamine (Gln)	T	Threonine
G	Glycine	W	Tryptophan
H	Histidine	Y	TYrosine
I	Isoleucine	V	Valine

as translocations (where the DNA is simply moved to elsewhere in the genome), which do not alter the relative fluorescence. Arrays can be high or low resolution and be targeted to specific portions of the genome. Essentially, it is a similar principle to a G-band karyotype where one is looking for missing or additional chunks of DNA. The difference is that the resolution of CGH allows it to detect much smaller differences.

DNA Microarray

DNA microarray is “gene chip” analysis that involves a glass microscope slide to which the gene sequences of interest are bonded to act as probes (for example, candidate genes). To this the fluorescently labeled patient sample containing hundreds or thousands of genes is applied and will hybridize to the complementary DNA. This is called *interrogation*, and a computer is used to detect the areas in which patient and control DNA do not hybridize to the same degree. Efforts are being made to develop phenotype-specific panels so that many of the known mutations that produce a specific clinical picture (for example, syndromic craniosynostosis) can be interrogated at one sitting.

DNA Sequencing

If an array does not detect a disorder, then gene sequencing can be used in which the base sequence of the gene of interest is read and errors determined. This is the most time- and resource-consuming form of genetic testing. For about 25 years, Sanger (chain termination) sequencing¹² has been the technique used, but this has been superseded by next generation (NextGen) methods that are automated large-scale genome analyses. Such high-throughput genome sequencing technologies have been used as a research tool but are being introduced into clinics as the costs fall. *Whole genome sequencing* (WGS) sequences the complete genome DNA. By contrast, extracting and sequencing only the exons (the portions that are transcribed to be made into proteins) has proved to be fast and accurate; this is called *whole exome sequencing* (WES). But as the introns are no longer considered “junk DNA” and the costs continue to fall, WGS is likely to displace WES in the long term. To interpret these data efficiently, one needs to sequence the affected individual and both unaffected parents as a trio to quickly discard benign sequence variations (CNVs and SNPs). One of the greatest challenges of NextGen technology will be the bioinformatics required to store and analyze so much data. One caveat is that most SNP-based diagnostics are

probabilistic (based on a computerized statistical analysis of chemical reactions) rather than deterministic, such as the microscopic observation of a gene duplication. Nonetheless, we are less than a generation away from an individual's whole genome sequence being entered into his or her electronic patient record.¹³ Once this information is available, genetic "testing" will simply be a matter of comparing the patient's recorded gene sequence to control data.

CREATING A BABY: SPECIFYING A BODY PLAN AND EARLY CRANIOFACIAL DEVELOPMENT

Fertilization sparks a series of events, creating a complete human body plan within 8 weeks. To achieve this, a single cell needs to be instructed to divide and assemble in a coordinated manner. By the third week, gastrulation occurs whereby a flat three-layered sheet of the embryo is formed comprising ectoderm, mesoderm, and endoderm. By this process, rostrocaudal,* dorsoventral, and left-right axes are established, giving cells "positional information." On completion of gastrulation, a notochord (primitive vertebral axis) is formed that signals to the ectoderm to induce the neural plate, which gives rise to all neural tissue (Fig. 18-2). This flat plate rolls up to form the neural tube, which develops into the central nervous system and from which the neural crest arises and migrates, contributing to numerous key structures in the head and neck. Either side

*The rostrocaudal axis is that which runs nose to tail in all vertebrates. This avoids confusion with anteroposterior in humans (erect in the anatomic position) and quadrupedal species and thus refers to their craniocaudal axis.

of the neural tube lies the paraxial mesoderm that is segmented in register with the neuraxis. This somitomeric mesoderm migrates and gives rise to the musculature of the craniofacial region, angioblasts, and contributes to the skull base and calvarium.¹⁴

Neurulation and the Rostrocaudal Axis

Neurulation is the process by which the neural plate rolls up to form the neural tube. During this process, the neural crest is formed (see section below) and eventually a clear craniocaudal difference visibly emerges. The rostral neural tube expands and becomes subdivided in early development into the forebrain (*prosencephalon*), midbrain (*mesencephalon*), and hindbrain (*rhombencephalon*). By the fifth week of gestation, this simple three-segment brain further develops, with the prosencephalon dividing into the rostral *telencephalon*, which will form the cerebral hemispheres, and the caudal *diencephalon*, which is recognizable by the optic vesicles extending from either side of it. The mesencephalon remains undivided, whereas the rhombencephalon (comprising segments called *rhombomeres*) can be morphologically divided into the *metencephalon* (future cerebellum and pons) and more caudal *myelencephalon*^{3,15,16} (medulla) (Fig. 18-3).

Hox Genes and Rostrocaudal Specification

In the trunk, each of the thoracic, lumbar, and sacral levels represents a unit of metameric segmentation, whereas in the cranial region, such segmentation is not morphologically obvious. The debate regarding the segmentation of the head has a long history. The first experimental evidence that segmentation exists in the cranial region was presented by Lumsden and Keynes. They demonstrated that the pattern of rhombomeres corresponded to the arrangement of the roots of the cranial nerves.¹⁷ This subdivision was subsequently supported at the molecular level by the expression of *Hox* genes, a family of homeodomain-containing genes that encode protein regulators of gene transcription.

Four (paralogous) groups (A through D) of sequentially numbered *Hox* genes (1 through 13) occur in humans. They are unique in that they are expressed in combinations along the longitudinal axis of the neural tube, each having a different cephalic boundary of expression¹⁸ (see Fig. 18-3). The different combinations of *Hox* genes at a specific point along the craniocaudal axis confer specific information relevant to that position.¹⁹ For example, retinoic acid is known to move the boundary of expression of *Hoxb-1* cephalically along the rhombencephalon. This changes the regional character of rhombomeres so that instead of giving rise to the trigeminal nerve, they now produce a duplicate facial nerve.²⁰ These homeotic genes are thus regulators of developmental patterning; by encoding transcription factors that influence batteries of other genes, they can be broadly considered master genes for regional specification.

The Neural Crest

The *neural crest*, which carries positional information from the brain into the face, is a key component of the head and neck, forming much of the connective tissues and peripheral nervous system of the head. This includes bones, cartilages, cranial ganglia, odontoblasts, corneal stromal fibroblasts, muscle fascia, vascular smooth muscle, dermis, and melanocytes. The neural crest arises as a distinct cell population at the border between neural and nonneural ectoderm. As the neural folds rise up to reach each other, but before their fusion to form the neural tube, the cells at the crest of this fold begin to delaminate, beginning at the level of the mesencephalon at 3½ weeks' gestation. These neural crest cells pass through interruptions in the basement mem-

Fig. 18-3 Segmentation of the craniofacial region. *Hox* gene expression correlates to the segmentation of the rhombencephalon (hindbrain), cranial nerve roots, and migrating neural crest streams.

brane to enter the mesodermal layer, at which point they migrate to form a substantial proportion of the facial mesenchyme. Studies reveal that migration follows specific routes with a craniocaudal correlation between the origin and destination of the neural crest. Ephrins and their receptors are mediators of cell contact-dependent interaction and have an important role in creating defined streams of cell migration.²¹ It may be considered that three major migratory pathways are taken by these cells^{22,23}:

1. The rostralmost stream migrates around the optic vesicle and contributes to the fronto-nasal process and the maxillary and mandibular processes of the face.
2. The otic vesicle divides the remaining cranial neural crest into the preotic crest, which migrates into the hyoid arch and contributes to the facial nerve ganglia.
3. The postotic crest that fills the third and fourth branchial arches contributes to glosso-pharyngeal and vagal nerve ganglia and the heart (cardiac neural crest), where it surrounds the truncus arteriosus (see Fig. 18-1).

These migrating neural crest cells express a combination of *Hox* genes appropriate to their origin from the rostrocaudal axis of the neural tube and carry this information into the branchial arches. The cells proliferate and signaling cues guide migration to their destination, where they are influenced by local signals; a failure of these processes to occur in an appropriate spatiotemporal sequence gives rise to a wide range of congenital abnormalities.²⁴ Therefore the neural crest can simplistically be considered to be carrying genetic information into the face and branchial arches to allow regional programs of development to be initiated.

Neurocristopathies and CHARGE Syndrome

Neurocristopathies are disorders of neural crest development and are broadly divided into defects of migration and morphogenesis (such as CHARGE syndrome) and tumors arising from neural crest tissues (such as neurofibromatosis). Given the major contribution of the neural crest to the craniofacial complex, a number of craniofacial malformations may be called *neurocristopathies*; these include hemifacial microsomia, 22q deletion syndrome (22q DS), DiGeorge syndrome, and Treacher Collins syndrome (discussed later in this chapter under Branchial Arch Syndromes).

CHARGE syndrome demonstrates the breadth of effects caused by these disorders; the acronym summarizes the key features: coloboma, heart defects, choanal atresia, retardation of growth and development, genital anomalies, and ear anomalies. Major and minor diagnostic criteria exist²⁵ (Fig. 18-4). Most cases are sporadic and 90% are associated with haploinsufficiency of *CHD7*, a transcription factor that interacts with genes essential for neural crest migration.²⁵ The other 10% of cases are thought to be mutations in other genes and the same features can be produced by teratogens such as retinoic acid; therefore, CHARGE is still a clinical diagnosis rather than a genetic diagnosis.²⁵

Fig. 18-4 A child with CHARGE syndrome. **A**, Typical facies with prominent forehead, broad nasal bridge, and left facial palsy. Note the similarity to the facies of patients with 22q DS. **B**, Characteristic triangular concha.

CHARGE patients are most likely to present to the ENT surgeon with choanal atresia or to the craniofacial team with cranial nerve dysfunction (for example, facial palsy), external ear anomalies (triangular concha), or cleft lip and palate (CL/P). Each of these issues is managed as in other individuals, but multidisciplinary coordination of care improves the family and patient experience. Feeding difficulties may be caused by lower cranial nerve palsies and may necessitate tube feeding. In addition to sensorineural hearing loss, semicircular canal anomalies may present as a lack of motor coordination, with delayed milestones but rarely dizziness. Most of these children are intellectually normal or near normal. Echocardiography and ultrasonography of the kidneys should be performed in all patients to screen for anomalies where early intervention may be important. Educational psychology is important in managing the developmental and behavioral aspects of this disorder.

CONCLUSION

As a consequence of neurulation, neural crest migration, and movements of the somitomeric mesoderm, the early cranial region comes to be dominated by the primitive brain dorsal to the notochord with the pharyngeal region below. At approximately the fourth gestational week, the head fold develops, and subsequently a number of bulges develop around the primitive mouth (stomodeum) that comprise the facial processes and pharyngeal arches. This primitive segmental arrangement undergoes great morphologic change to become the recognizable structures of the head and neck. Subsequent craniofacial development can be subdivided into development of the brain and midline facial development, fusion of the facial processes and palate, development of the pharyngeal arches, cranial vault development, and development of the cranial base. Each will be described in turn in the next section, along with its clinical correlates.

Concepts for Understanding Congenital Facial Differences

The basic structure of the face is formed between the fourth and eighth weeks of gestation, but facial development continues into puberty, once dentoskeletal maturation is complete. Toward the end of the fourth week, five processes appear at the base of the prosencephalic vesicle that will eventually unite to form the face (Fig. 18-5). A midline process called the frontonasal process and the lateral paired maxillary and mandibular processes (derived from the first pharyngeal arch) surround the stomodeum to unite to form the facial structures. By the fifth week, the frontonasal process is flanked on either side by the nasal placodes and will form the intermaxillary segment, a precursor of the philtrum of the upper lip, the premaxillary part of the upper jaw, and the primary palate. By the end of the sixth week, the frontonasal process engulfs the nasal placodes, creating a hooded appearance as each placode sinks into the underlying tissues to create the olfactory pit. The frontonasal process now consists of both lateral and medial nasal processes, and the olfactory pit communicates with the buccal cavity by the nasobuccal channel. Meanwhile, the maxillary process meets the lateral nasal process and fuses with it, and by the seventh week, it meets the medial nasal process and its fellow of the opposite side. Thus the union of the upper maxillary processes is completed.

Fig. 18-5 The facial processes.

Classification Based on Developmental Processes

Various classifications of craniofacial conditions are often complex and confusing and are rarely widely adopted. My former career as a developmental biologist has led to a personal working classification based on the mechanisms of craniofacial development. This allows the developmental mechanisms, genes, and syndromes to be related to each other and provides a framework on which to associate new clinical, genetic, and scientific information.

MIDLINE FACIAL DEVELOPMENT

The development of the frontonasal process is a key component of normal facial morphology. However, signals to pattern the midline of the face arise at gastrulation, when an area rostral to the notochord called the *prechordal plate* is formed. Experimental evidence demonstrates that midline facial development involves a stepwise mechanism, relaying signals from the prechordal plate to the ventral forebrain (prosencephalon), onto the migrating neural crest, and then the facial ectoderm, which finally establishes signaling centers around the olfactory pit that influence the morphology of the developing face (Fig. 18-6). Experimental manipulation (surgical or genetic) of this process can produce midline facial excess or deficiency, mirroring the clinical spectrum of orbital hypertelorism and holoprosencephaly (HPE), respectively; the earlier in development this is performed, the more severe the phenotype. This stepwise mechanism intimately links the development of the brain with the facial midline.

The formation of the prechordal plate requires the signaling of Nodal in concert with TDGF1 through the TGF β signaling pathway, together with a repression of bone morphogenetic protein (BMP) activity.²⁶⁻²⁸ Once established, the prechordal plate signals to the overlying ventral prosencephalon by synthesis of the secreted signal encoded by SHH. The SHH signal activates the homeobox gene *Six3* in the ventral forebrain, establishing a feedback loop that maintains SHH expression.²⁹ This forebrain SHH signal is communicated through the migrating neural crest to the facial ectoderm, where a new SHH signaling region is initiated. Inhibition of

Fig. 18-6 Midline facial development is a stepwise sequence of signaling.

this SHH activity or surgical removal of the neural crest resulted in a failure of the frontonasal process to develop normally and anomalies resembling HPE.³⁰

Ectodermal expression of SHH and adjacent *Fgf8* create a signaling region called the *frontonasal ectodermal zone*, which appears to coordinate patterned outgrowth of the frontonasal process.³¹ Excision of this region leads to hypoplasia of the frontonasal process and a facial cleft phenotype. By contrast, application of SHH protein or overexpression of SHH lead to orbital hypertelorism and duplicated midline structures.³² Once the frontonasal process has formed, FGF signaling around the nasal pits appears to be vital to morphogenesis. Inhibiting their activity leads to apoptosis and midfacial hypoplasia, whereas application of FGF2 leads to increased cell proliferation and an enlarged frontonasal process.³³

Median Facial Dysgenesis With Deficiency: The Holoprosencephaly Spectrum

Midline defects of the craniofacial complex have been described by Tessier³⁴ as 0-14 clefts in which he includes conditions with deficiency and excess. Deficiency includes orbital hypotelorism, arhinencephaly, and absent premaxilla and prolabium together with various cleft lip configurations. Such features are part of the *holoprosencephaly* (HPE) spectrum. HPE is a defect of the forebrain in which there is a failure of cleavage of the prosencephalon into the paired telecephalic vesicles that form the cerebral hemispheres. It is etiologically heterogeneous and a feature of a number of syndromes. It is classified neuroanatomically as *alobar* (a single monoventricular cerebrum), *semilobar* (rudimentary cleavage of the cerebrum), and *lobar*, where there are two cerebral hemispheres, but callosal hypoplasia or agenesis may occur. Pituitary dysfunction, particularly diabetes insipidus, is common and should be actively managed. Traditionally, it is said that the “face dictates the brain,” in which the severity of the facial deformity is correlated to underlying cerebral pathology, but this is not the situation in approximately 20% of cases.^{35,36}

Cyclopia is the most severe facial phenotype in which there is a median eye, proboscis, and the nose is absent. *Ethmocephaly* comprises arhinia, proboscis, and paired but hypoteloric eyes. *Cebocephaly* is the presence of a single nostril pit, and finally, there is median cleft lip, which is associated with absence or hypoplasia of the primary palate. Not all median cleft lips are associated with brain anomalies, and individuals with normal intelligence and head circumference are said to have *binderoid clefts* and are not considered holoprosencephalic.³⁷ Microforms exist, including a single maxillary incisor and the absence of septal cartilage, labial frenulum, and philtrum. However, diagnosis at this subtle end of the spectrum becomes problematic, because many of the features may occur without central nervous system anomalies, and the diagnosis of HPE may depend more on the context in which the abnormality is diagnosed.^{36,38} Although many clinical cases can be categorized accordingly, the clinical presentation of HPE is in fact a spectrum ranging across this classification.^{36,39}

Gene mutations have been identified in roughly 20% of cases with variable expressivity and penetrance. Many of these genes are components of the signaling pathways outlined above: *NODAL*,⁴⁰ *TDGFI*,⁴¹ *SIX3*,⁴² *SHH*, and its receptor *PATCHED1*,⁴³ as well as its downstream target *GLI2*.^{44,45} In very general terms, mutations that reduce the SHH signal lead to deficiency and those that increase it lead to excess.

Binder Syndrome

Perhaps one of the more subtle expressions of median facial deficiency is *Binder syndrome*, the syndrome of maxillonasal dysplasia detailed by von Binder in 1962⁴⁶ based on three cases. The anterior nasal spine is replaced by a pit in the maxilla known as the *fossa prenasalis*, which was first described by Zuckerkandl in 1882.⁴⁷ It is regarded as autosomal recessive with low penetrance.⁴⁸ Binder facies have been associated with chondrodysplasia punctata, and features such as brachydactyly should stimulate screening investigations.⁴⁹

Clinical Features

Patients with Binder syndrome have a typical facies with nasal flattening and malar hypoplasia. Nasal features are the consequence of a lack of foundation for the nose (absent anterior nasal spine and short septum) leading to flattened alae, an acute columellar-labial angle, and an abnormal nasofrontal angle (Fig. 18-7). A pathognomonic finding that differentiates this from other causes of midfacial hypoplasia is a lack of a palpable anterior nasal spine. Maxillary hypoplasia may be significant, leading to a class III skeletal relationship with anterior open bite. There may be a deficiency of nasal lining, the frontal sinuses may fail to pneumatize, and atlantoaxial defects

Fig. 18-7 Binder syndrome. A 1½-year-old girl with nasal hypoplasia. The lateral view shows a suggestion of relative prognathism.

may occur.⁵⁰ Radiographs are of little use in diagnosis, but a lateral cephalogram is important for documenting the occlusal relationship.

Principles of Correction

Given the psychosocial factors, nasal correction is often performed when the patient is approximately 10 years of age. The mildest forms can be addressed using standard rhinoplasty techniques; other methods include the use of a cantilevered bone or costochondral graft through a bicoronal approach, together with batten grafts to the alae. Medpor implants have been tried, but I avoid using alloplast in the nose because of the extrusion rate. If there is a lack of nasal tip support, a hinged septal flap to rotate the tip forward can be used; if there is a lack of bony dorsum, an L-shaped iliac bone graft can be used. Both may be performed through vestibular incisions and combined with onlay bone grafting around the piriform aperture to address the maxillary hypoplasia.⁵¹

Mild malocclusions can be treated with orthodontics alone; more significant abnormalities will require a combined approach. It is best to leave orthognathic correction until dentofacial growth is complete, and it should be noted that a standard LeFort I osteotomy will not improve nasal projection. However, if a significant skeletal class III relationship exists, a LeFort I osteotomy can be performed in the standard manner.

Median Facial Dysgenesis With Excess

The 0-14 cleft with excess is described as consisting of the cranium bifidum with duplication of the crista galli, orbital hypertelorism, nasal septal duplication, and a median cleft of the maxilla and lip.³⁴ It is very heterogeneous in its presentation and has many names, but is most commonly called *frontonasal dysplasia* (FND)⁵² (Fig. 18-8). It comprises some or all of the features above and a broad nasal root, with or without notching or clefting of the nasal alae. Soft tissue excess is manifest as a surplus of skin, hair (widow's peak), and fibrofatty tissue in the midline. Intracranially, median lipomas can also be observed, and in severe cases the median cranial base is disrupted by an encephalocele.

Fig. 18-8 Frontonasal dysplasia. Note the severe orbital hypertelorism and broad forehead with a widow's peak, together with widely spaced and notched nasal alae.

FNDs are a usually sporadic phenomenon of midline craniofacial excess, with few inherited cases. Other anomalies are common, but syndromic forms are rare and include acromelic frontonasal dysostosis, manifest as FND with tibial hypoplasia and preaxial polydactyly. It was hypothesized that mutations in the SHH pathway were responsible for this: *Gli3* is an important downstream target of SHH.^{53,54} Like FND, *orbital hypertelorism* is regarded as causally heterogeneous and is typically sporadic but a number of syndromes exhibit hypertelorism including Apert syndrome (*FGFR2*), Gorlin syndrome (*PTCH1*) and Greig syndrome (*GLI3*).⁵⁵

Genetic mutations have been identified within a family of homeobox genes resulting in a classification of some cases into types 1 through 3. Type 1 (frontorhiny) is a distinct phenotypic subset with autosomal recessive loss of function in the transcription factor *ALX3*.⁵ Type 2 FND has similar features, with abnormal skin and hair development, and is due to homozygous mutation in *ALX4*.^{56,57} In contrast to the *ALX3* form, it lacks the characteristic long philtrum with prominent ridges. Heterozygous mutations have been associated with parietal foramina.⁵⁸ Type 3 FND is caused by mutations in *ALX1* and exhibits a severe phenotype, with bilateral cleft lip and primary palate that are not seen in the *ALX3* and *ALX4* forms.⁵⁹ In contrast to *ALX3* and *ALX4*, *ALX1* is expressed in the early stages of neural crest development, and its dysfunction inhibits neural crest migration in the frontonasal stream.⁶⁰ Although *ALX4* may act downstream of the SHH pathway, how *ALX* genes interact with other signaling systems in craniofacial development remains to be determined.⁶¹ But knockdown of *alx1* leads to defective neural crest migration into the frontonasal and maxillary processes, indicating that this may underlie type 3 FND.⁶⁰

Craniofrontonasal Dysplasia

A distinct syndromic form of FND is *craniofrontonasal dysplasia* (CFND) in which orbital hypertelorism occurs in tandem with bicoronal craniosynostosis and a variety of extracranial abnormalities. It is inherited in a sex-linked fashion, but unusually, girls predominate and have a more severe phenotype. CFND is a consequence of a mutation of *ephrin-B1* (*EFNB1*) expressed in the frontonasal neural crest.^{62,63} Ephrin-B1 has a role in the proper migration of the cranial neural

crest, and disruptions lead to craniofacial malformations.⁶⁴ The developmental mechanisms of *EFNB1* remain to be elucidated, but there are indications that apart from signaling hierarchies, other factors that regulate cell proliferation, migration, and adhesion play a role in facial morphogenesis.

Clinical Features

All patients with CFND have unilateral or bilateral coronal synostosis, orbital hypertelorism, and other facial anomalies, such as CL/P, anterior open bite, hypoplastic ear deformities, and Stahl's ear. Eye abnormalities are related to oculomotor disorders and downslanting palpebral fissures. Dry, frizzy hair and longitudinal grooving of the nails are characteristics of patients with CFND. Limb anomalies such as clinodactyly, syndactyly, and brachydactyly are common, as is a characteristic shoulder girdle abnormality with neck webbing, prominent scapulas, and a hypoplastic clavicle. Management of these patients is the same as for others with syndromic craniosynostoses, with early frontoorbital remodeling to correct the calvarial morphology and orbital osteotomies to correct the hypertelorism after eruption of the permanent dentition.⁶⁵ Surgical correction is discussed in Chapter 25.

DEFECTS OF FACIAL FUSION: FACIAL CLEFTS

The facial processes consist of a core of neural crest–derived and somitomeric mesoderm (mesenchyme) enclosed in an ectodermal jacket. Each will have an associated nerve and vessel; the frontonasal process contains the ophthalmic nerves and vessels. The first arch vessel is the maxillary artery and the nerve is the trigeminal nerve with divisions to the respective maxillary and mandibular processes.

The argument of whether neural crest cells truly migrate was settled more than 20 years ago by techniques that can label individual cells and track their migration within live embryos in the laboratory.⁶⁶ Likewise, the mesodermal penetration versus fusion theory of how the facial processes coalesce points toward fusion as the mechanism. Proliferation of the mesenchyme leads to an increase in the size of the facial processes as they grow toward each other and fuse in a coordinated fashion. During the fifth gestational week the nasal placodes begin to sink into the frontonasal process, creating medial and lateral processes as distinct thickenings on either side of the developing nasal pit. At this stage the maxillary process fuses with the lateral nasal process; as they merge, the ectoderm in the floor of this groove forms a solid epithelial cord, which will eventually canalize to form the nasolacrimal duct, connecting the orbit to the nasal cavity. By the seventh week, the maxillary process almost reaches the midline, where it fuses with the paired medial nasal processes. The maxillary process will form the upper lip, upper jaw, and secondary palate, whereas the philtrum and primary palate are derived from the medial nasal process; the lateral nasal process forms the ala of the nose. Meanwhile, the mandibular process grows medially to join the fellow of the opposite side to complete the formation of the lower jaw. The maxillary process also fuses longitudinally to the mandibular process; the degree of this fusion determines the width of the mouth.

Signaling Networks Control Outgrowth and Patterning of the Facial Processes

The growth and patterning of the facial processes are tightly regulated by numerous signaling pathways and regions that control epithelial-mesenchymal interactions, cell proliferation, and cell differentiation. Members of the TGF β subgroup called the *bone morphogenetic proteins* (BMPs), *Bmp2* and *Bmp4*, are important for outgrowth of the facial processes. Ectopic application can lead to duplicated structures, increased cell proliferation, and activation of the downstream genes

Msx-1 and *Msx-2*.⁶⁷ By contrast, inhibition leads to decreased proliferation and apoptosis.⁶⁸ Work has shown that the BMPs can alter the shape of the frontonasal process and create species-specific differences in morphology. Similarly, FGF signaling around the nasal pits is important, with decreased FGF signaling leading to a failure of contact between the processes, resulting in failure of fusion.³³ The BMPs act upstream of the FGFs, and the *Msx* genes are the downstream effector molecules for both pathways.³³ *MSX-1* mutations have been associated with nonsyndromic CL/P and syndromic CL/P with oligodontia.^{69,70} Nonsyndromic CL/P associations have also been reported with multiple FGFs and supported by mouse models and may constitute up to 3% to 5% of nonsyndromic CL/P cases.^{71,72}

The *Wnt signaling molecules* (the name comes from *wingless* in *Drosophila* and *integrated-1* [*int1*] in mice when they were found to be the same gene) are secreted signaling molecules, and a number of Wnts are known to be expressed in the developing facial processes. Particularly, *Wnt3* is expressed in the facial ectoderm of the tip of the maxillary and medial nasal (but not lateral nasal) process.⁷³ *WNT3* homozygous loss results in cleft lip only and amelia.⁷⁴ *WNT9a* is close to *WNT3* on the chromosome and is expressed in the tips of all the facial processes but not the secondary palate. Although further investigation is necessary to dissect how the *Wnt* genes effect facial morphogenesis, this pathway appears important in mediating FGF signaling loops and interacts with the BMP pathway.

Fusion of the facial processes involves a series of morphogenetic mechanisms:

- As the processes draw near, the periderm (outer layer of the bilaminar fetal epidermis) is shed, mediated by apoptosis; it is suggested that this promotes cell junction adhesion between the two epithelia.⁷⁵
- Thereafter, epithelial filopodia at the primary site of fusion begin to establish bridges between the processes resulting in an epithelial seam. This breaks down to allow confluence of the underlying mesoderm. This mechanism has been primarily studied in the secondary palate, the key debate being whether these cells undergo programmed cell death or transition into mesenchymal cells.⁷⁶

Evidence so far suggests that the cells undergo apoptosis, whereas perhaps a small population undergoes epithelial-mesenchymal transition.⁷⁷ Failure of fusion leads to facial clefts, and this can be caused by failure of one of the following:

- Neural crest migration
- Cell proliferation
- Adherence between processes
- Programmed cell death during fusion
- The normal morphogenetic processes after initial stages of fusion

All these processes are under genetic and epigenetic control.

Clefts of the upper lip (including Tessier 1 and 2 clefts) occur as a consequence of a failure of normal fusion of the maxillary and medial nasal processes. Cleft lip may be associated with cleft palate (discussed later) and may be syndromic and nonsyndromic. By contrast, atypical facial clefts are considered sporadic phenomena that are etiologically heterogeneous. Defects in the fusion of the lateral nasal and maxillary processes lead to the oroocular cleft (Tessier 3). Insufficient fusion between the maxillary and mandibular processes causes macrostomia (Tessier 7 cleft). Clefts 6 and 8 are actually hypoplastic disorders discussed later.

The Problem of the Tessier 4 and 5 Clefts

Tessier clefts 4 and 5 of the face do not map to known fusion sites. This poses a problem to explain in simple embryologic terms. It may be that these are caused by amniotic bands, but be-

cause they occur in a relatively predictable fashion, this seems unlikely. They may be caused by external pressure or internal hemorrhage, leading to tissue necrosis. Another theory may be that there is a failure of fusion of the maxillary and lateral nasal processes with a degree of embryonic regulation occurring. Embryonic regulation is the initiation of reparative mechanisms when part of the embryo is lost by trauma or experimental manipulation. Given the discrete signaling centers around the facial processes, it is possible that a degree of incomplete regulation occurs leading to these clefts.

Another possibility is that the problem of the Tessier 4 and 5 clefts may be manmade, in that the classification system attempts to classify a diverse range of craniofacial morphologies into a limited number of groups. There is a tendency in the literature to make the embryology fit the classification rather than the reverse. Each cleft is unique and a consequence of numerous mechanisms, such as failure of proliferation, failure of fusion, mechanical effects, and regulation.

DEVELOPMENT OF THE PALATE

The oronasal cavity begins as a single large cavity, but between the six and tenth weeks of gestation, the formation of the palate partitions it into separate spaces. The palate is derived from the frontonasal process that forms the primary palate, which constitutes the anterior bony part of the upper jaw (the premaxilla), which bears the incisor teeth. Paired lateral palatine processes positioned on the oral surface of the maxillary process appear at the sixth week of development and form the secondary palate. Cell proliferation causes them to grow medially and inferiorly down either side of the tongue. During the seventh week, over a period of hours, these palatine shelves elevate to achieve their anatomic position above the tongue.

Palatal Elevation

A key event in palatogenesis is the elevation of the palatal shelves. Most theories invoke an intrinsic force within the shelves that overcomes extrinsic forces and culminates in palatal shelf elevation. Studies have implicated hyaluronic acid as a likely mediator; this glycosaminoglycan carries a high negative charge that attracts water, creating an amorphous gel.⁷⁸ The increase in hyaluronic acid causes the palatal shelves to swell, and this swelling force is directed by longitudinal bundles of type I collagen oriented from the base to the shelf edge. Palatal mesenchyme cells are contractile and secrete neurotransmitters, which may control contractility and glycosaminoglycan degradation, thereby playing a modulatory role in palatal morphogenesis.⁷⁹

During the period of shelf elevation, there is an increase in head height but not head width, creating space above the tongue into which the shelves move. The tongue muscles become functional about the time of shelf elevation, and conversely, inhibition of fetal movement has been suggested to cause palatal clefting.⁸⁰ Descent of the tongue is a key event, which if restricted by mandibular hypoplasia such as in Pierre Robin sequence, may result in cleft palate. Although the exact combination of mechanisms remains to be fully characterized, it appears that an intrinsic elevation mechanism of the shelves in concert with extrinsic environmental factors and mandibular morphogenesis allows the appropriate temporospatial sequence of events.

Palatal Fusion

The *medial edge epithelia* (MEE) of the fusing shelves forms a midline seam, and then rapidly disappears to allow mesenchymal continuity. During this period, the ectoderm on the nasal surface differentiates into epithelium characteristic of the respiratory tract, while the oral surface forms

the nonkeratinizing oral mucosa. Within the mesenchyme, the palatal shelves will ossify to form the hard palate, while myoblasts migrate into the posterior palate to contribute to the soft palate. Palatal fusion is complete by 12 weeks.

Molecular Signaling and Palate Development

Much of our knowledge of molecular signaling and palate development is based on the mouse model using targeted mutagenesis or manipulation of the palatal shelves in explant culture. SHH is present in much of the early oral epithelium and is a key signal in promoting palatal shelf outgrowth.⁸¹ SHH in palatal explant cultures stimulated cell proliferation. *Fgf10*, secreted by the palatal mesenchyme together with its receptor *Fgfr2*, in the overlying epithelium are also critical for palatal shelf outgrowth. *Fgf10* knockout mice have cleft palate with hypoplasia as do those with targeted mutation of *Fgfr2* in epithelium.⁸² In embryos with loss of *Fgf10* or *Fgfr2*, there was a drop in SHH expression indicating that *Fgfs* may act through SHH to effect cell proliferation and palatal shelf growth. SHH may act through the BMP pathway: SHH protein beads activate *Bmp2* expression in culture, and *Bmp2* can increase cell proliferation in the palatal mesenchyme.⁸³ The *Bmp* signaling regulates expression of the transcription factor *Msx1* and is also responsible for maintaining SHH expression in the palatal epithelium.

In the mouse model, there is a degree of regionalization along the rostrocaudal axis of the morphologically homogeneous palatal shelves. For example, *Msx1* is expressed anteriorly whereas *Tbx22* is expressed posteriorly in the presumptive soft palate mesenchyme. *Tbx22* appears to be required for palatal bone formation with *Tbx22* null mutants exhibiting cleft palate or submucous cleft palate (SMCP).⁸⁴ Mutations in *TBX22* have been identified as a cause of X-linked syndromic cleft palate with ankyloglossia termed CPX.⁸⁵

In addition to the rostrocaudal patterning, there are signals that are involved in mediolateral patterning of the shelves (note that the medial surface becomes the nasal surface of the shelf after elevation). *Dlx5* is coexpressed with *Fgf7* in the medial mesenchyme of the palatal shelf. Loss of *Dlx5* leads to a loss of *Fgf7* and an expansion of the SHH expression onto the medial epithelium (Fig. 18-9). Such embryos had an expanded oral aspect to the palate and a malformed soft palate.⁸⁶

p63 is an ectoderm-specific p53-related transcription factor that acts upstream of *Dlx5* and *Dlx6*, regulating their expression. p63 regulates morphogenesis of surface ectoderm through multiple signaling pathways.⁸⁷ Mutations in p63 are responsible for *ectrodactyly ectodermal dysplasia clefting syndrome* (EEC), which is an autosomal dominant syndrome comprising a cleft hand and abnormal skin, teeth, and hair, together with CL/P. p63 binds to an enhancer upstream of *IRF6* (interferon regulatory factor 6), which is a direct target of p63.⁸⁸ *Irf6* is expressed at the edges of the fusing palatal shelves and facial processes. Loss of *Irf6* leads to a hyperproliferative epidermis that fails to differentiate, causing cleft palate and mirroring a number of ectodermal dysplasia syndromes.⁸⁹ Compound mutants of p63 and *Irf6* exhibited cleft palate with retention of the periderm cells obstructing the fusion of the palate. *IRF6* mutations have been identified in Van der Woude syndrome⁹⁰ and may have a role in nonsyndromic clefts.⁹¹

TGFβ3 has a prominent role in fusion of the palatal shelves. Palatal shelves in *TGFβ3*^{-/-} mutant mice elevate and make contact but fail to fuse with persistence of the MEE. Both *TGFβ1* and *TGFβ3* are expressed in the MEE, and there is a degree of redundancy, because a knockin of *TGFβ1* into the *TGFβ3* locus partially rescues the cleft phenotype. In addition, a significant reduction in programmed cell death was detected, indicating that *TGFβ3* regulates apoptosis in the MEE.⁹²

Fig. 18-9 Signaling in the palate. Palatal development involves cellular proliferation with growth of the palatal shelves down the side of the tongue, and elevation and fusion in the midline. *FGFs*, *SHH*, *BMPs*, and *Msx* genes are part of a signaling network that control growth of the palatal shelves. Additionally, *FGFs* through the action of the transcription factor *Dlx5* act to suppress *SHH* and specify a medial-lateral identity to the palate. Note that the medial surface of the palate becomes the nasal surface after elevation of the palatal shelves. (*BMP*, Bone morphogenetic protein; *Fgf*, fibroblast growth factor; *Ptc*, patched; *Shh*, Sonic hedgehog.)

Genetic and Environmental Factors in Palatal Clefts

Any failure in the timing or mechanism of these many processes may result in cleft palate, so it is not surprising that CL/P is one of the most common craniofacial malformations. The basis of nonsyndromic clefting is not easily explained by a single gene model, and it was thought that a multifactorial threshold model was likely; for example, after a certain number of mutations occur in the genetic background, a phenotype is seen. In this situation, a greater number of mutations would result in a more severe phenotype and a higher risk of recurrence. However, a large Norwegian population study did not find this association, and new models need to be found.⁹³ Environmental factors include the mother's use of anticonvulsant medications, steroidal agents, alcohol, smoking, and an excess of retinoids (vitamin A); folate deficiency has been implicated as well, whereas the genes associated with sporadic CL/P include *TGFβ3*, *IRF6*, and *MSX1*. Increasingly, the importance of gene-gene and gene-environment interactions is being realized; for example, it has been demonstrated that smoking and alcohol use in the presence of *MSX1* mutations have a synergistic effect in causing isolated cleft palate (iCP).^{94,95}

A number of genes have been identified for syndromic CL/P and iCP, such as Apert syndrome, for which cleft palate is more commonly related to the S252W mutation in *FGFR2*, possibly altering the balance of *FGFR2* expression and events at the MEE. A targeted point mutation in *Fgfr2*^{C342Y/-/-} that leads to ligand-independent activation of the receptor results in increased lateral palatal mesenchyme proliferation, reduced GAG accumulation, and a delay in elevation.⁹⁶

SYNDROMIC CLEFT PALATE

CL/P and iCP are discussed in Chapter 22; however, the more common syndromes are reviewed next.

Pierre Robin Sequence

Defined as a triad of micrognathia, glossoptosis, and airway obstruction (Fig. 18-10), *Pierre Robin sequence* is a well-recognized clinical entity, but variable in terms of presentation and diagnostic criteria.⁹⁷ It may affect up to 1:8500 births.⁹⁸ More than 90% of cases exhibit cleft palate that is characteristically wide and U-shaped. The sequence is hypothesized to be that reduced mandibular growth leads to a tongue that fills the oronasopharynx and physically obstructs the elevation of the palatal shelves. Affected babies have significantly smaller mandibles and tongues than age-matched controls at birth, but significant increases in size dramatically enlarge the airway, and by 2 years of age this is manifested as an improvement in airway control and feeding.⁹⁹ More than 40 syndromes with Pierre Robin sequence have been described; the most common include Stickler syndrome and velocardiofacial syndrome (22q). Although some genetic mutations have been reported, no specific gene causes Pierre Robin sequence.¹⁰⁰

Management

Airway Airway obstruction is a defining feature of Pierre Robin sequence, and although there is posterior displacement of the tongue into the hypopharynx, the airway may be compromised at many levels, including central abnormalities, and pharyngeal and laryngeal anomalies. Airway compromise leads to growth retardation, decreased feeding, and increased energy expenditure from the work of breathing; management of airway obstruction is the same as for any craniofacial patient. Bedside endoscopic assessment to evaluate the degree and level of obstruction is recommended, but this may require examination under anesthesia and direct laryngoscopy and bronchoscopy to rule out multilevel obstruction and guide intervention. The airway improves in the majority of cases in the first year, which is attributed to mandibular catch-up growth.

Fig. 18-10 Pierre Robin sequence. Mandibular hypoplasia is observed, with a wide complete cleft of the secondary palate. This infant demonstrates respiratory compromise, as evidenced by sternal retraction. Note the feeding tube in place to ensure that adequate nutrition is provided despite airway issues.

Surgical management of the Pierre Robin sequence airway is usually not required, but, when performed, centers on the use of tongue-lip adhesion, and more recently, mandibular distraction. Tongue-lip adhesion involves the anterior anchoring of the posterior tongue with a nonabsorbable circummandibular suture and the anterior tongue to the lower lip mucosa. There has been debate about the benefit of this procedure with regard to improved feeding, because it does disrupt the normal swallow mechanism. A GILLS scoring system to guide patient selection has been proposed that is based on the following¹⁰¹:

- Gastroesophageal reflux
- Intubation before surgery
- Late presentation
- Low birth weight
- Syndromic diagnosis

Mandibular distraction is specifically targeted to the obstruction caused by the tongue base and aims to increase pharyngeal airway diameter. The principles of distraction are discussed in Chapter 30. Internal or external distractors can be used; the procedure involves bilateral mandibular osteotomies to lengthen the body of the mandible. Potential complications include damage to tooth germs, nerve injury, wound complications, and malunion. Large-scale studies have yet to report their outcomes, but objective radiographic studies have demonstrated increases in airway size; overcorrection is recommended.⁹⁷

Feeding Maintaining adequate respiratory stability during feeding is essential. This is mainly accomplished by using modified bottles or nasogastric tube feeding. Nasogastric tube feeding is rarely required after 1 year of age in isolated Pierre Robin sequence cases; children with prolonged issues or requiring gastrostomy tube feeding are usually those with associated syndromes.

It is critical to monitor the infant's weight gain. Failure to gain weight should prompt investigation and intervention. Reflux can unbalance feeding and respiration by causing airway inflammation and edema, increasing secretion production and compromising the swallow mechanism. It is important that reflux be considered, identified, and treated early on to optimize feeding.

Further Assessments All Pierre Robin sequence babies should have an ophthalmologic assessment between 6 and 12 months or at the time of a molecular genetic diagnosis. Newborns are hyperopic, so any myopia at 6 to 12 months should raise suspicion of Stickler syndrome; although not quantified, attention tests are used to pick up early visual problems. Other investigations are geared toward searching for features of other known syndromes, assessment of hearing, and monitoring speech development.

Stickler Syndrome

Stickler syndrome is an autosomal dominant mutation of *Col2a1*, *Col11a1*, or *Col11a2*, with incomplete penetrance called *types 1, 2, and 3*, respectively. They are procollagen genes that are expressed in the cartilage and vitreous, thereby affecting the development of the mandible and eyes. The syndrome comprises Pierre Robin sequence features, eye defects, progressive sensorineural hearing loss, joint hypermobility or hypomobility, and variable epiphyseal dysplasia (manifested as joint pain, degeneration, or dislocation).

Eye Defects

Eye defects comprise a progressive severe myopia (80%), vitreous degeneration, and the most emergent problem, retinal detachment. There should be a high index of suspicion for retinal detachment. Babies and young children will not declare visual problems until the second eye becomes involved; thus ophthalmologic screening should be performed in confirmed cases. Retinal tears and detachment occur peripherally at first, then intrude on central vision. A careful family

Fig. 18-11 This 13-year-old boy with Stickler syndrome was born with micrognathia and a wide complete cleft of the secondary palate. He is myopic and has additional ophthalmologic findings consistent with Stickler syndrome. He had a tracheostomy for severe airway compromise and associated sleep apnea, which followed a pharyngeal flap. After takedown of the flap and additional mandibular growth, he was able to be decannulated. He wears bilateral hearing aids.

history from the parents regarding eye problems may suggest Stickler syndrome in a child with cleft palate. It has been suggested that prophylactic 360-degree cryoretinopexy will reduce the risk of detachment later in life.¹⁰² Many patients develop visual loss from progressive glaucoma.

Clinical Features

Facies include maxillary hypoplasia and dental issues such as malocclusion, natal teeth, and enamel hypoplasia. Progressive high-frequency sensorineural hearing loss is present in 80% of children with Stickler syndrome, but symptoms are not seen until the third decade (Fig. 18-11). All affected individuals have musculoskeletal anomalies, including mild to moderate epiphyseal dysplasia. Many develop premature joint disease, especially of the hip, and spinal deformities also occur.

Management

Patients with Stickler syndrome are managed in the same way that Pierre Robin sequence babies are managed, with ophthalmic screening. Abnormalities should prompt referral to a genetics specialist, and referral to an orthopedic surgeon may be considered.

Van der Woude Syndrome

Van der Woude syndrome is an autosomal dominant disorder of orofacial anomalies with variable penetrance that commonly manifests as CL/P and distinctive lower lip pits. It is the most common form of syndromic CL/P, affecting 1 to 2:100,000 live births, or 1% to 2% of CL/P patients. There is no racial or sex predilection, and 25% have minimal findings, such as absent teeth or lower lip pits. An accurate family history is essential to diagnosis, but 30% to 50% have de novo mutations; the examiner should look for an autosomal dominant inheritance, bearing in mind the variable penetrance. The fact that individuals may have CL/P or iCP indicates that these conditions are not entirely independent.

Fig. 18-12 Van der Woude syndrome. This is the classic position of the distinctive lower lip pits associated with this syndrome. This child was not troubled with serous discharge from these well-developed sinuses.

Van der Woude syndrome has been identified as a 1q32 deletion, and a number of mutations in *IRF6* have mapped to this locus.¹⁰³ It is part of a family of helix-turn-helix transcription factors that control interferon; it is expressed along the edges of the fusing palate and facial processes, but the function of *IRF6* remains unknown.

Clinical Features

The hallmark features of Van der Woude syndrome are the CL/P and lower lip pits (in 70% of patients) (Fig. 18-12). The lower lip pits typically sit on either side of the midline, but aberrant positions have been described. They may communicate with minor salivary glands and hence secrete saliva. Excision of the pits must therefore include the surrounding glandular tissue to prevent mucocoele formation. Lower lip pits exist in 2% of the normal population and may be associated with preauricular sinuses. SMCP is common and should be excluded, and it is important to search specifically for the triad of features and speech assessment for hypernasality. Extraoral anomalies include limb anomalies and popliteal webs; in this instance, it is called *popliteal pterygium syndrome* and is also caused by mutations in *IRF6* in 97% of cases (rather than the 76% of Van der Woude cases).

DEVELOPMENT OF THE PHARYNGEAL ARCHES AND BRANCHIAL ARCH SYNDROMES

The *pharyngeal arches* are a segmental series of structures in the cephalic region from which the nerves, muscles, and skeletal components of the pharyngeal apparatus are derived. Externally, between each arch lies a pharyngeal cleft; internally, there is the equivalent pharyngeal pouch. Each arch consists of mesenchyme that is mainly derived from the neural crest and some pre-muscle mesoderm that has migrated from the somitomeres. The generic constituents of each arch are a cartilage rod, an aortic arch, a nerve, muscle, and derivatives of the arch endoderm.

The first pharyngeal arch is called the *mandibular arch*, yet it also gives rise to the maxillary processes. Its skeletal component is Meckel's cartilage, which gives rise to the sphenomandibular ligament, malleus, and incus. The aortic artery of this arch will become the maxillary artery, and the muscles of this arch are all innervated by the trigeminal nerve. The second arch is called the *hyoid arch*, and its skeletal component forms the lesser horns and body of the hyoid, stylohyoid ligament, styloid process, and stapes. The muscles of facial expression are derived from this arch mesoderm and are innervated by the facial nerve. The stapedial artery supplies this arch; its course passes through the stapes, and regression during the third fetal month creates the unique morphology of this bone. This artery may persist into adult life, where it is at risk during middle

ear surgery. Gestational hemorrhage from this artery has been cited as a cause for some branchial arch anomalies, such as hemifacial microsomia.¹⁰⁴

The first pharyngeal cleft gives rise to the external auditory meatus, whereas the remaining clefts are covered by a downward growth of the second arch called the *operculum*, and the space underneath is called the *cervical sinus*. This eventually expands into the smooth contours of the neck as development proceeds. The third arch gives rise to the internal carotid artery and the greater horn of the hyoid, with its only muscular derivative being the stylopharyngeus, innervated by the glossopharyngeal nerve. The fourth and sixth arches are less well studied, but the fourth arch gives rise to the muscles and cartilages of the larynx and lower pharynx; these are innervated by the vagus nerve. The arteries of the fourth arch form the right subclavian artery and aorta. The sixth arch may contribute to the laryngeal and tracheal cartilages; the fifth arch does not form in higher mammals.

The endoderm lines the internal aspect of the pharyngeal arches. Early in development, the pharyngeal endoderm begins to evaginate toward the ectoderm and assumes a slitlike morphology under the constraining influence of a web of actin cables. The endoderm of these pouches gives rise to the thyroid, thymus, and tonsil. At the dorsalmost part of the pouch, endodermal *Bmp7* signals to the ectoderm of the pharyngeal cleft to induce the epibranchial placodes.¹⁰⁵ These placodes are thickenings of the ectoderm at the dorsal-caudal rim of the arch that will produce neuroblasts, which migrate and condense to form the cranial nerve sensory ganglia. The first pharyngeal pouch deepens and expands to form the middle ear cavity, while its connection to the pharynx persists as the Eustachian tube. Commensurate with this, the first pharyngeal cleft elaborates a cord of epithelium that canalizes, creating the external auditory meatus. Between the cleft and the pouch persists a membrane, the *membrana tympani*.

Signaling Systems Pattern the Arches to Establish Normal Facial Morphology

Each pharyngeal arch gives rise to a range of structures, each of which is different from its neighbor. Therefore every arch requires a positional identity to ‘know’ where it is and what to form. Initially, it was thought that all this information was carried into the arch by the migrating neural crest, but a role for the pharyngeal endoderm has become apparent.^{106,107} The pharyngeal endoderm appears to be the source of signals that establish pattern in the pharyngeal arches; for example, specific combinations of homeobox genes in the first arch are responsible for the different tooth types.^{108,109}

In the first arch, SHH from the endoderm appears to be important in establishing the localized expression of *Fgf8*. Experimental manipulation of SHH expression can reduce or increase the *Fgf8* expression, resulting in abnormal patterning of the lower jaw.¹¹⁰ *Fgf8* plays a role in restricting *Bapx1* expression to a specific area of the first arch. Excess *Fgf8* inhibits *Bapx1* and leads to loss of the jaw joint. Manipulating the expression pattern of *Bapx1* leads to changes in development and position of the jaw joint.¹¹¹ *BAPX1* abnormalities have been identified in some patients with oculo-auriculo-vertebral syndrome (hemifacial microsomia).¹¹²

In the search for animal models with abnormal pharyngeal arches, a zebrafish mutant called *van gogh* fails to form pharyngeal pouches. Accordingly, when the otherwise-normal neural crest streams reach the arches, they become disorganized, and abnormal skeletal structures form.¹¹³ *van gogh* was found to be a loss of function of *tbx1*, a T-box transcription factor strongly implicated in DiGeorge syndrome.¹¹⁴ In mouse, knockout of *Tbx1* results in a 22q deletion-like phenotype, whereas mutations in *TBX1* have been identified in individuals with 22q DS.¹¹⁵⁻¹¹⁸ Little is known about the mechanism of *Tbx1* or its gene targets, although the *Fgfs* are candidates. *Fgf8* knockouts have features similar to *Tbx^{-/-}* mice, with normal *Tbx1* expression indicating that *Fgf8* lies downstream in the signaling pathway. By contrast, Wnt signaling through β -catenin appears to lie upstream of *Tbx1*.¹¹⁹⁻¹²⁰

22q Deletion Syndrome (Velocardiofacial Syndrome/DiGeorge Syndrome)

22q deletion syndrome (22q DS) was described by Shprintzen et al¹²¹ based on the assessment of 12 children with similar anomalies, all of which referred for velopharyngeal insufficiency. It comprises a “CATCH-22” of anomalies (Fig. 18-13):

- Cardiac anomalies
- Abnormal facies
- Thymic aplasia
- Cleft palate
- Hypocalcemia

22q DS shares many features with DiGeorge syndrome, and both were noted to possess a chromosome deletion at 22q; this (heterozygous) deletion encompasses at least 32 genes, including *TBX1*.¹¹⁷⁻¹²² Other genes in the 22q DS region may also cause the characteristic phenotype by acting as genetic enhancers or modifiers, but *TBX1* mutations in patients that are 22q positive also

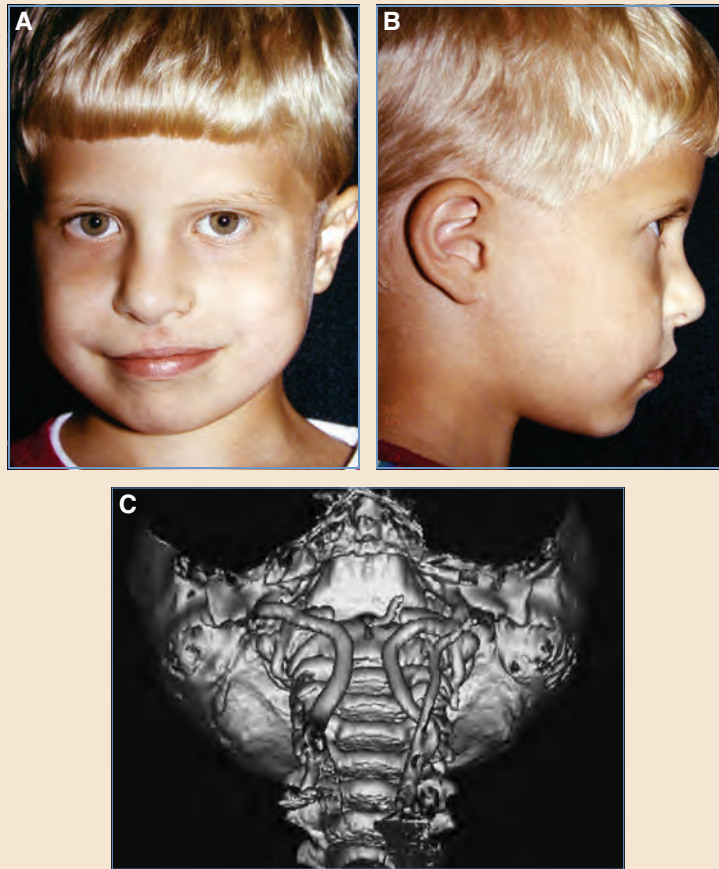

Fig. 18-13 22q deletion syndrome. **A** and **B**, This 7-year-old boy had been receiving speech therapy since he was 3 years of age. He has a short, immobile soft palate with a submucous cleft. He exhibits a broad nasal dorsum with narrow alar bases, flattened zygomatic arches, platybasia, and vertical maxillary excess. At the time of his planned pharyngoplasty, it was noted that he had medially displaced carotid arteries. **C**, CT angiography of the carotids of another patient with the same syndrome.

replicate the characteristics of the syndrome and make *TBX1* a key suspect in the pathogenesis of 22q DS. DiGeorge syndrome affects 10% of 22q DS patients: this is a developmental defect that additionally involves the third and fourth pharyngeal pouches with thymic aplasia and hypoparathyroidism manifested as hypercalcemia.

Clinical Features

Velopharyngeal Insufficiency Twenty-four percent of these patients present with iCP or SMCP, which is characterized by the triad of notched posterior hard palate (absence of posterior nasal spine), a bifid uvula, and zona pellucida because the muscle fails to meet at the midline of the palate. These individuals have a limited ability to open their mouths, adenoidal hypoplasia, and platybasia. Platybasia creates a deep pharynx with poor lateral wall movement that contributes to the velopharyngeal insufficiency, and it also makes access difficult for pharyngeal flap surgery. Speech outcomes are typically poorer as a result of anatomic and neurocognitive learning deficits. The cleft, often compounded by patent Eustachian tubes, predisposes the patient to middle ear disease and consequent hearing impairment, but sensorineural hearing loss may also occur.

Cardiac Anomalies Cardiac anomalies are present in 85% of patients with craniofacial anomalies, including ventriculoseptal defects (most common), aortic coarctation, pulmonary stenosis, and tetralogy of Fallot. Such conotruncal cardiac defects may present with recurrent chest infections, compounded by immunodeficiency in the DiGeorge group. Craniofacial surgeons must be aware that up to 25% of patients with velopharyngeal insufficiency have medially deviated or midline carotid arteries.¹²³ Before starting surgery, one should palpate the pharyngeal walls for pulsations to avoid raising pharyngeal flaps immediately adjacent to the vessels. The pharynx may be too deep to palpate the carotids reliably, and some surgeons advocate a CT or MR angiogram of the carotids to determine their proximity to the surgical site.

Facial Features Facial features characteristic of these patients include a long facial shape with vertical maxillary excess, flat malar eminences, and a broad nasal bridge. There may be mild epicanthal folds or pseudohypertelorism. The temporomandibular joint is relatively displaced posteriorly, leading to a class II occlusion. Such features are difficult to discern at birth.

Associated Factors Associated factors include mild hypotonia in early childhood, small stature, learning difficulties, psychosis in later life, immune issues from thymic aplasia, and abnormal dermatoglyphics.

Management

The palate is repaired in the standard fashion, but outcomes are poorer and the need for revision surgery is more common than in nonsyndromic cases. Careful assessment of the palate to inform selection of the primary procedure can produce results close to a nonsyndromic group, but these children require more intense speech therapy and take much longer to achieve such results.¹²⁴ Children with 22q DS should be seen by an immunologist to be assessed for immune compromise; until this occurs, they should not receive live vaccines. If they are not immune competent, the blood products they receive should be irradiated. Individuals with DiGeorge syndrome should have annual thyroid and calcium assessments and a CBC.

Oculo-auriculo-vertebral Spectrum (Hemifacial Microsomia and Goldenhar Syndrome)

Commonly termed *hemifacial* (craniofacial) *microsomia* and known by many other names, *oculo-auriculo-vertebral spectrum* (OAVS) is a syndrome that is characterized by a variable constellation of features related to the maldevelopment of the branchial arches.^{125,126} It is the most common craniofacial syndrome after CL/P, with an incidence of approximately 1:5600.¹²⁷ OAVS is bilateral in 10% to 20% of cases and has a male-to-female ratio of 3:2 and a right-to-left ratio

Fig. 18-14 Goldenhar syndrome presents in a spectrum ranging from mild to severe. **A and B**, This patient has hypoplasia of the soft tissue, mandibular hypoplasia, macrostomia, microtia, and epibulbar dermoid. **C**, A patient with Goldenhar syndrome with bilateral deformities, including asymmetrical mandibular hypoplasia, bilateral macrostomia, incomplete bilateral cleft lip (occult on the left side), nasolocular clefting, and preauricular remnants. **D**, A 9-year-old child with mandibular hypoplasia, auricular remnant, soft tissue deficiency, right macrostomia, and epibulbar dermoid.

of 3:2. The phenotypic subset known as *Goldenhar syndrome* (Fig. 18-14) constitutes approximately 4% of this group.¹²⁸ No minimum diagnostic criteria have been agreed on, and it is widely accepted that preauricular malformations and microtia represent microforms of the condition. Up to one third of cases may be bilateral. Microtia may be the only sign of OAVS in the early years, until mandibular hypoplasia becomes more apparent.

OAVS is a sporadic disorder, but there is some evidence for some inheritance with autosomal dominant inheritance in 2% to 10% of cases.¹²⁹ The inherited form is more likely to have bilateral involvement, but the patient is less likely to have hearing loss, epibulbar dermoids, and abnormalities of the external auditory meatus. The etiologic mechanism of OAVS has yet to be determined; hemorrhage of the stapedia artery has been suggested, based on animal models and case reports.¹³⁰ Numerous associations with maternal conditions and medications including thalidomide and retinoids have also been noted, suggesting that epigenetic mechanisms are

important. It should be noted that dysregulation of *BAPXI* has been reported, probably as a result of epigenetic factors.¹¹² This explains the high proportion of discordant monozygotic twins, why other genes are implicated, and the high correlation with maternal IVF treatment.¹³¹ It is also interesting to note that a gene that is critical for the position and development of the jaw joint is implicated in OAVS.¹¹¹

The underlying issue is a tissue deficiency. It remains to be seen whether the tissue deficiency is caused by a failure of neural crest specification, migration, proliferation, or abnormal signaling in the first arch or whether it is caused by cell death (either programmed or secondary to vascular trauma).

Clinical Features

The clinical features of oculoauriculovertebral spectrum syndromes are variable and wide ranging and are best summarized by the OMENS and OMENS+ classifications.^{132,133} The acronym stands for **o**rbit, **m**andible, **e**ar, **n**erve, and **s**oft tissue. The + denotes extracranial anomalies, and a phenotypic assessment tool exists to aid standardization of assessment.¹³⁴

Orbital Dystopia The orbit may be of abnormal size, abnormal position, or both; this is a result of hypoplasia of the maxilla and zygoma. In the Goldenhar subset, epibulbar dermoids are situated on the sclera, typically in the inferolateral part of the eye; these are masses of gray-white to yellowish tissue and vary in size. Lipodermoids, which are mobile yellow masses, are less common. The presence of epibulbar dermoids may indicate other eye anomalies such as ptosis, lacrimal drainage issues, and motility disorders.¹³⁵

Mandibular Hypoplasia Mandibular hypoplasia is regarded as the cornerstone of the disorder, because it is directly correlated with the severity of the other features.¹³² It leads to malocclusion and deviation of the chin to the affected side with mouth opening (Fig. 18-15). The hypoplasia was originally classified by Pruzansky,¹³⁶ was modified by Vento et al,¹³² and was assimilated into the OMENS classification guiding surgical management:

M1 is characterized by a small mandible with a short ramus and an intact glenoid fossa.

M2 indicates a small and abnormally shaped ramus and is subdivided:

Type A: Symmetrical glenoid fossae

Type B: A severely hypoplastic condyle that sits in an abnormal position

M3 has an absence of the temporomandibular joint.

M1 and M2A may be addressed with distraction techniques, whereas M2B and M3 require reconstruction, typically with costochondral rib grafts.

Ear Anomalies Preauricular tags, pits, and sinuses may occur, and the external auditory meatus may be malpositioned and hypoplastic. The relationship of the facial nerve may be abnormal, and this is important in surgical planning. Conductive hearing loss is common as a consequence of middle ear anomalies. By contrast, the inner ear is rarely affected. The auricular morphology was described by Meurmann and incorporated into the OMENS classification:

E1: There is hypoplasia, but all structures are present.

E2: There are remnants of cartilage and skin, with external auditory meatus atresia.

E3: The pinna is almost completely absent; the lobule usually remains in an anterior and inferiorly displaced position.

Nerve Defects The facial nerve is most commonly affected. It may have an unusual course or exhibit paresis, and the parotid nerve may be absent. Facial palsy is estimated to occur in 22% to 45% of patients with 22q deletion syndrome and may be caused by neural or muscular hypoplasia. Most facial nerve grading systems cannot be applied accurately, because the asymmetry at rest is partly the result of dentoskeletal factors. Other nerves may be smaller, such as the motor nerve to the masseter muscle; this should be taken into consideration when it is used to drive a free functioning muscle transfer.

Fig. 18-15 Hemifacial microsomia. This child has type III mandibular deformity, soft tissue hypoplasia, and lobule-type microtia.

Soft Tissue Defects Macrostomia (Tessier 7 cleft) is common, often minor, and is easily missed. Cleft palate is also common, especially in individuals with Goldenhar syndrome; the palate may be hypoplastic and deviate on examination; about one third of patients may have velopharyngeal insufficiency.¹³⁷

Other Anomalies Spinal anomalies, especially those affecting the cervical vertebrae, are common, such as C2-3 fusion, hemivertebrae, spina bifida, and craniocervical base anomalies. Such intracranial anomalies as hydrocephalus and intracranial lipomas as well as developmental delay may also occur.¹³⁸ Other defects include congenital heart disease, pulmonary anomalies, genitourinary malformations, and musculoskeletal defects.¹³³

Management

As with all complex craniofacial conditions, assessment and treatment should occur within a craniofacial team. In a neonate, multidisciplinary management with optimization of the airway and feeding is vital to define the extent of the disorder. If the palate is cleft, a standard repair is performed at about 6 to 12 months of age, bearing in mind the stability of the airway. If macrostomia is present, this may be corrected at the same procedure. Thereafter, a period of monitoring and orthodontics follows, during which jaw growth is assessed and its function optimized.

Ear reconstruction is performed at approximately 10 years of age, once the child is old enough to understand the procedure, be compliant, and possess sufficient costal cartilage for harvest. Jaw reconstruction may be performed by a variety of methods. Early reconstruction of Pruzansky IIb and III by costochondral rib grafting is an established method, and subsequent growth of the graft makes it suitable for early reconstruction.^{139,140} More recently, distraction osteogenesis has been employed for Pruzansky I and IIa (and above) mandibles and for postreconstructed mandibles.¹⁴¹ Conceptually, this technique is excellent for this reconstructive problem. A caveat, however: its use must be carefully considered in skeletally immature patients in which there is insufficient evidence to support its use because of the high reoperation rate and cost relative to orthognathic surgery at maturity.¹⁴² Although orthognathic surgery at maturity is associated with stable results, there is a higher secondary surgery rate than for other patient groups.¹⁶

Treacher Collins Syndrome (Mandibulofacial Dysostosis)

The previously described syndromes underscore the importance of normal neural crest proliferation, migration, and patterning to the development of the face. The posteriormost stream of the neural crest contributes to the heart (see Fig. 18-1) and links the cardiac defects seen with 22q DS to the underlying developmental process. Although the exact mechanisms remain unknown in 22q DS and OAVS, the neural crest defect in Treacher Collins syndrome has been elucidated.

Treacher Collins syndrome was named after the eminent British ophthalmologist, Edward Treacher Collins, after his description of 11 cases¹⁴³ (11 years after the original description by Berry¹⁴⁴). It is a first branchial arch syndrome that shares many features with OAVS but generally occurs symmetrically. Treacher Collins syndrome affects 1 in 25,000 to 50,000, with an equal sex distribution and no racial predilection. It has an autosomal dominant inheritance with a variable penetrance, but 60% are new mutations.¹⁴⁵ The gene coding for the disorder is *TCOF-1*. The protein product is called *treacle* and is implicated in preribosomal RNA processing; it affects the production of a mature ribosomal RNA for translation into protein. This product is required for neural crest cell proliferation, and haploinsufficiency leads to neural crest apoptosis and consequent hypoplasia of neural crest–derived tissues.^{146,147} Like 22q DS syndrome, it is often regarded as a neurocristopathy.

Clinical Features

The key feature of Treacher Collins syndrome is the so-called *birdlike facies*, in which skeletal hypoplasia in the first arch primarily affects the orbits, mandible and midface, ears, and soft tissues (Fig. 18-16). The similarity to OMENS makes it straightforward for grouping the clinical features.

Orbital Defects Zygomatic hypoplasia with deficiency of the lateral orbital wall leads to a loss of lower eyelid support. The lower lids are hypoplastic with coloboma, absent lashes medially, and downslanting palpebral fissures.

Mandibular and Midface Anomalies The hypoplasia affects the zygoma, mandible, and to a lesser extent the temporal bones. Tessier regarded this as a combined 6, 7, and 8 cleft, with cleft 6 referring to hypoplasia at the zygomaticomaxillary junction, cleft 7 involving hypoplasia of the zygoma with microtia and macrostomia, and cleft 8 being characterized by hypoplasia at

Fig. 18-16 A child with Treacher Collins syndrome, exhibiting severe symmetrical mandibular hypoplasia with ocular coloboma and hypoplastic zygomas, leading to downslanting palpebral apertures.

the frontozygomatic junction. The mandible has a short ramus, body, and prominent antegonial notch, creating a short posterior facial height and a convex facial profile.¹⁴⁸ This causes retrognathia and class II malocclusion, with an anterior open bite. The Pruzansky classification is routinely used for this group.

Ear Defects Patients with Treacher Collins syndrome typically present with symmetrical microtia, with or without atresia of the external auditory meatus, sensorineural deafness, and tongue-shaped sideburns. A hypoplastic middle ear and ossicles is an almost universal finding, and more than 95% have mild to moderate hearing loss as a result of external auditory meatus atresia or ankylosis of the ossicles. A bone-anchored hearing aid (BAHA) is used in these patients.

Nose and Mouth Defects Treacher Collins infants present with choanal atresia or stenosis. In later life the nose may exhibit a broad dorsum with an osteocartilaginous hump and inadequate tip projection. The palate is high and narrow, and more than one third of patients have cleft palate. An additional 30% present with velopharyngeal insufficiency or submucosal cleft palate.¹⁴⁹

Management

As with all craniofacial syndromes, a child with Treacher Collins syndrome should be managed within a multidisciplinary framework that focuses on airway, feeding, vision, and hearing.

Airway The airway is the overwhelming priority: the maxillary hypoplasia constricts the nasal passages, leading to choanal stenosis. Micrognathia with a posteriorly positioned tongue will obstruct the oropharyngeal and hypopharyngeal spaces. Because babies are obligate nasal breathers, and the pharyngeal airway of affected newborns is additionally compromised, urgent airway control soon after birth is essential. A spectrum of airway difficulties may be present and can be managed in the same way as for any craniofacial case.

Feeding Because of airway issues, feeding may be difficult and compounded by a cleft palate. Management, monitoring, and treatment will be as for any child with a cleft palate. Special attention is given to the timing of cleft palate closure, in view of the effect it may have on a compromised airway.

Vision Pediatric neuroophthalmologic assessment is useful to determine acuity, corneal exposure, and extraocular muscle function. If there is corneal exposure, correcting the coloboma is a priority.

Hearing ENT evaluation and formal audiometry, such as the auditory brainstem response test, are essential to plan the fitting of either BAHA or cochlear implants in patients with Treacher Collins syndrome. If one ear has normal function, it is rare to intervene on the contralateral side.

Surgical Management

At birth, airway considerations take priority, and multidisciplinary assessment should occur early to optimize feeding. If the cornea is exposed, conservative measures are instituted until the child is old enough to undergo surgical correction. If the coloboma is small and well managed, repair can be delayed or be combined with palate repair. Most small colobomata can be closed using established eyelid reconstruction principles, with local flap reconstructions used for those involving more than 50% of the eyelid. Between 9 and 12 months in most centers, palate repair is performed in the standard fashion, but this may be delayed for airway considerations. Much of the management of the jaw and ear is similar to that for OAVS; in addition, midface augmentation can be performed to provide lower lid support and improve facial contour. Such midface augmentation can be performed with split calvarial bone grafts or custom implants.¹⁵⁰ Soft tissue suspension, such as a mask lift, can be performed and canthopexies are essential.¹⁵¹ At skeletal maturity, orthognathic surgery is used to improve occlusion, but relapse is common and formal rhinoplasty may be requested to improve appearance.^{148,152}

Fig. 18-17 A child with Nager syndrome. Individuals have severely hypoplastic mandibular features, similar to Treacher Collins syndrome, in concert with radial ray deficiency.

Nager Syndrome

Nager syndrome is characterized by mandibulofacial dysostosis and radial ray deficiency (Fig. 18-17). It is mainly sporadic, but some cases are inherited. It is caused by a heterozygous mutation of the *SF3B4* gene on chromosome 1 in most cases.

Clinical Features

The features of Nager syndrome are similar to those of Treacher Collins syndrome, together with radial ray deficiencies, such as radial aplasia and hypoplasia, radioulnar synostosis, and hypoplastic and triphalangeal thumbs. These children are of low to normal intelligence, and palatal clefting is common, particularly manifested as a hypoplastic palate. Genitourinary abnormalities may also be associated, and other anomalies such as those of the lower limb have been reported but are uncommon. Management is the same as for Treacher Collins patients.

CRANIOSYNOSTOSIS AND CALVARIAL DEVELOPMENT

The developing brain grows at a rapid rate and to accommodate this, the calvarium must expand into postnatal life. This expansion is achieved through two mechanisms: first, the resorption of cranial bone on the dural surface of the calvarium and deposition on the exterior; second, the cranial sutures contribute to osteogenesis by allowing the formation of new bone at the periphery. The sutures close postnatally in a coordinated manner after the brain has achieved its full size. Craniosynostosis is the condition in which premature fusion of a suture occurs, restricting growth between the fused bones and reorienting this growth in an abnormal manner, which results in an abnormal head shape. The shape depends on which suture (or sutures) are fused (see Chapter 23).

The craniosynostoses can be classified as nonsyndromic and syndromic, with nonsyndromic presenting as isolated premature suture fusions, and syndromic being more complex, typically presenting with multiple suture fusions and/or other anomalies. The classic syndromic cranio-

synostoses include Apert syndrome, Crouzon syndrome, and Pfeiffer syndrome. Because they also affect the cranial base, they will be considered in the section on cranial base.

Developmental Anatomy

The development of the skull begins at about 25 days' gestation, originating from both the neural crest and the cranial mesoderm. The skull comprises the neurocranium, which houses the brain, and the viscerocranium, which is derived from the branchial arches and forms the face. The neurocranium consists of the cranial base, also called the *basicranium* or *chondrocranium* (referring to its endochondral origin), and the calvarium that is formed by ossification in membrane and creates the frontal, parietal, squamous, temporal, and part of the occipital bones. The maintenance of sutures is dependent on the presence of the dura.¹⁵³ Initially thought to have a mechanical role, the dura is the source of numerous signaling molecules that are involved in coordinating cranial morphogenesis.

Centers of ossification are seen for the paired frontal and parietal bones at 8 weeks' gestation, and by 14 weeks there is widespread ossification of all bones of the calvarium. Ossification begins by condensation of the mesenchyme cells of the skeletogenic membrane. There may be single or multiple closely spaced centers of ossification for each bone, and these coalesce and spread outward; the advancing edge is called the *osteogenic front*. Ossification expands radially until two areas of ossification confront each other, creating a suture. The sutures are simple adaptive ankyloses between the neighboring calvarial bones; these allow the brain to expand to reach its adult dimensions by growth perpendicular to the orientation of the suture. Mapping studies using transgenic mice have demonstrated that the coronal and sagittal sutures represent a boundary between the neural crest and mesoderm-derived calvarium.¹⁵⁴

Signaling Mechanisms in Suture Development

Once a suture has formed, it needs to remain patent to accommodate brain growth and lay down new bone at the osteogenic front. As elsewhere in the body, conserved signaling mechanisms govern the process of ossification; syndromic craniosynostoses have been found to be caused by mutations in *FGFR* genes among others, and the expression of these molecules has provided clues to the mechanism of suture formation and closure¹⁵ (Fig. 18-18). *Fgf9* is expressed at high levels in the suture mesenchyme, underlying dura and overlying skin.¹⁵⁵ *Fgf2* is expressed in the sutural mesenchyme and its receptors, *Fgfr1* and *Fgfr2*, in the osteogenic fronts indicating a paracrine function. FGF2 is known to stimulate osteoblast proliferation and inhibit differentiation,¹⁵⁶ whereas application of FGF4 on the osteogenic front accelerates suture closure and mimics the FGFR syndromes.¹⁵⁵ *Fgfr1* is expressed in differentiating osteoblasts and *Fgfr2* is expressed in the proliferating osteogenic precursors. *Bmp2* and *Bmp4* are also expressed in the osteogenic fronts, with levels falling after birth: FGF signaling activates *Msx1* and BMP activates both *Msx1* and *Msx2*, with both being expressed in the suture with *Msx2* levels dropping after birth. *Msx2* has a role in maintaining suture patency, and mutations in *MSX2* have been identified in Boston-type craniosynostosis.¹⁵⁷ Signaling networks appear to change after birth with SHH/*Ptc* expression appearing in the osteogenic front at the end of embryonic development. SHH may interact with *Bmps* through a *Ptc*-dependent pathway to maintain suture patency postnatally.¹⁵⁵ The secreted BMP antagonist *Noggin* is expressed postnatally in the suture mesenchyme of patent but not fusing sutures. *Noggin* prevents suture fusion in vitro and in vivo, and it has been hypothesized that

Fig. 18-18 The fibroblast growth factor signaling pathway. There are over 23 known secreted FGF ligands that bind to the extracellular domain of the FGFR. Ligand binding leads to a conformational change that triggers a dimerization of the FGFRs. Dimerization leads to intracellular activation of the downstream MAP kinase pathway. Ligand-receptor specificity varies, as does dimerization. For example, FGF binding can trigger heterodimerization or homodimerization of FGFRs, which may translate into differential intracellular signaling. The *FGFR2* Apert mutation affects the ligand-binding region (A) between the IgI and IgII loops leading to enhanced ligand binding. *FGFR* mutations associated with Crouzon, Pfeiffer, and Jackson-Weiss syndromes mostly affect the IgIII loop leading to dimerization without the need for ligand binding: constitutive activation. (FGF, Fibroblast growth factor; TK1, tyrosine kinase region 1; TK2, tyrosine kinase region 2; TM, transmembrane.)

premature *Noggin* downregulation may lead to craniosynostosis; however, no *NOGGIN* (or *BMP*) mutations have been identified in human cases.¹⁵⁸

Although much remains to be understood regarding suture growth and fusion, the role of the FGF and related pathways is beginning to emerge from a combination of transgenic mice and in vitro assays. One model suggests that FGFs are secreted by osteoblasts and diffuse toward the osteogenic fronts¹⁵⁹ (Fig. 18-19). At low concentrations, the FGF stimulates proliferation of sutural stem cells and *Fgfr2* expression. As the bone matrix advances toward the osteogenic front, the FGF concentration rises and the proliferating cells initiate differentiation into *preosteoblasts*. This is accompanied by downregulation of *Fgfr2* and upregulation of *Fgfr1* expression, whereupon they begin to secrete matrix and are called *osteoblasts*.¹⁵⁹ Exogenous application of FGF2 upregulates *Twist* expression in the sutural mesenchyme. *Twist*'s role is to inhibit the terminal differentiation of osteoprogenitor cells into osteoblasts. FGF2 has stimulatory and inhibitory effects, and in-

Fig. 18-19 FGF control of proliferation and differentiation at the calvarial suture osteogenic front. A proposed model is based on a balance of FGFR1 and FGFR2 expression regulated by the concentration of FGF ligand. (FGF, Fibroblast growth factor.)

hibitory effects appear to be mediated in a *Twist*-dependent fashion.¹⁵⁶ Loss of function of twist disinhibits osteoblast differentiation, leading to premature closure of the suture, and this loss of function has been identified as the cause of Saethre-Chotzen syndrome.^{160,161} It appears that the quantity of TCF12-Twist heterodimers is critical in coronal suture development. *TCF12* haploinsufficiency causes coronal synostosis in humans, and haploinsufficiency of both *Tcf12* and *Twist* in mice leads to a severe bilateral coronal synostosis.¹⁶² For example, *Fgfr3* exhibits weak expression in skeletogenic membrane and stronger expression in skull base cartilage. However, mutations in *FGFR3* cause Muenke syndrome and may reflect a coronal suture-specific function of *FGFR3*.¹⁶³

DEVELOPMENT OF THE CRANIAL BASE AND FACIAL DYSOSTOSES

The morphologically complex cranial base suspends the face and ossifies from cartilage (chondrocranium). The chondrocranium consists (from rostral to caudal) of the paired trabeculae cranii that lie between the paired nasal capsules, the *sphenoid* (comprising paired orbitosphenoid and alisphenoid cartilages), and the basioccipital cartilage derived from the paired parachordal cartilages (either side of the notochord). A detailed account of the developmental anatomy of the cranial base has been published elsewhere.¹⁵

The chondrocranium is completed by 12 weeks' gestation, and primary ossification centers emerge within this unified cartilaginous structure¹⁶⁴ (Fig. 18-20). The synchondroses are the joints that remain between the bone centers. The sphenoethmoidal fuses at 6 years and the intrasphenoid ossifies at birth. By contrast, the sphenooccipital synchondrosis plays an important role in postnatal growth and fuses around puberty.¹⁶⁵ Synchondroses can be considered a mirror image of an epiphyseal growth plate of a long bone in terms of morphology and possibly chemical

Fig. 18-21 Carpenter syndrome is rare. Kleeblattschädel deformity (cloverleaf skull) is characteristic of the syndrome and refers to the head shape as a consequence of multisuture synostosis.

naling, have been identified, linking the laboratory knowledge of *hedgehog* and suture biology to the clinic.¹⁷¹

Clinical Features

Carpenter syndrome is characterized by craniosynostosis, preaxial polydactyly of the feet, brachydactyly, syndactyly, obesity, and developmental delay (Fig. 18-21). Synostosis typically begins at the sagittal suture, then to the lambdoid and coronal sutures in succession. The anterior cranial fossa is underdeveloped, with shallow orbits that have an unusually “tall” morphology. Patients may exhibit hypotelorism or hypertelorism, and the eyes may feature ptosis; corneal opacity and optic atrophy may occur. There is no correlation between cranial dysmorphology and neurologic abnormality.¹⁷² Ears are low-set and may be rotated posteriorly; preauricular sinuses and fistulas may occur. Developmental delay is usual, but cases of normal intellect have been reported.¹⁷³ Other anomalies, such as umbilical hernia/omphalocele, short stature, hypogonadism and obesity, have all been reported.

The FGFR and Related Craniosynostosis Syndromes

Apert syndrome has a relatively narrow phenotype. By contrast, other syndromes are much more heterogeneous in their phenotype and overlap clinically. Genetically, the syndromes of this group have multiple different mutations and will be considered together. FGFRs have multiple roles during ossification through regulation of chondrocyte and osteoblast proliferation and differentiation as well as differing effects at each of the various cranial sutures. By acting on multiple processes during suture/synchondrosis formation, great clinical heterogeneity is observed.

Apert Syndrome

Originally described by Wheaton in 1894,¹⁷⁴ Apert syndrome is known eponymously for French physician Eugène Apert, who described a series of cases. It is the second most common facial dysostosis syndrome after Crouzon syndrome. The incidence is 1:160,000 live births, with most cases being sporadic, but autosomal dominance has been reported.

Fig. 18-22 Apert syndrome. **A** and **B**, Kleeblattschädel deformity (cloverleaf skull). The lateral view shows ventriculoperitoneal shunts in place. **C** and **D**, A 6-month-old infant with Apert syndrome and airway compromise requiring early tracheostomy.

Phenotype

The phenotypic features of Apert syndrome can be grouped into craniosynostosis with intracranial pressure problems, midfacial hypoplasia, symmetrical syndactyly of the hands and feet, and other features (Fig. 18-22).

Craniosynostosis and Intracranial Pressure Children with Apert syndrome typically present with a brachycephalic head shape as a result of bicoronal synostosis and a large anterior fontanel that forms a bregmatic bump (volcano sign), because the increased pressure pushes against areas of weakness in the vault. It may also be associated with multiple suture synostosis and cloverleaf skull, in which case mental retardation can be profound and the prognosis is poor. The anterior fontanel remains patent for a prolonged period if it is left untreated.

Raised intracranial pressure occurs in 43% of Apert syndrome patients, but learning difficulties are more common, likely because of other brain anomalies, such as hydrocephalus, agenesis of the corpus callosum, hypoplastic white matter, and ectopic gray matter. Developmental delay

is mostly mild, and the individual may attain a high level of mental function.¹⁷⁵ Raised intracranial pressure in syndromic synostoses is not purely a matter of cerebrocranial disproportion; in fact, the Apert cranial volume is greater than in the normal population.¹⁷⁶ A complex interplay of other factors contributes to intracranial hypertension, including obstructive hydrocephalus, anomalous venous drainage that creates venous hypertension with “back pressure” on the CSF, and obstructive sleep apnea that leads to increased CO₂ and therefore cerebral venous dilation.¹⁷⁷

Midfacial Hypoplasia Premature fusion of the sphenoccipital, sphenofrontal, sphenovomerine, and vomeromaxillary sutures in children with Apert syndrome leads to midfacial hypoplasia, with specific implications for the jaws and orbits.^{178,179}

Exorbitism, a protrusion of the globe as a result of reduced orbital volume, is caused by verticalization of the orbital roof and the hypoplastic inferior orbital rim. The ethmoids are “prolapsed” inferiorly between the orbits, bringing the cribriform plate almost as low as the equator of the globe and possibly accounting for the orbital hypertelorism and divergent visual axes.¹⁸⁰ As a result, the globe is situated anteriorly and the eyelids may be incompetent, leading to corneal exposure; this has been called *malignant exorbitism* and mandates early ocular protection. Other mechanisms contribute to visual dysfunction, such as optic nerve atrophy (papilledema) resulting from raised intracranial pressure. Extraocular muscle abnormalities may also contribute to disorders of conjugate gaze. *V-pattern exotropia* (divergent upgaze and esotropic downgaze) is more common in Apert syndrome than in Crouzon syndrome, possibly because of the absence of the superior rectus and architectural abnormalities of the extraocular muscles.¹⁸¹ This affects the maxilla to a greater degree than the zygoma and is a function of the reduced growth of the skull base; as a result, the pterygomaxillary fissure is virtually obliterated. An anterior open bite with premature posterior contact occurs, and the alveolar arch faithfully reflects the maxillary hypoplasia with a narrow crevicolike morphology to the hard palate; 75% of patients have a cleft palate with variable expressivity.¹⁸² This results in a crowded pharynx and a narrow nasal airway and may cause severe respiratory distress, especially during the period of obligate nasal respiration. The necessity of airway interventions is common in infants, whereas obstructive sleep apnea is frequent in older patients, and sleep studies are often required for monitoring. Almost all patients have otitis media, with effusion that persists into adult life, with more than half developing a permanent conductive hearing loss.¹⁸³

Hand Anomalies The asymmetrical syndactyly of the hands and feet seen in children with Apert syndrome is detailed in Chapter 45. The key features are complex or complicated syndactyly of the middle three rays where the tips (Greek *acros*) may be joined, a shortened radially deviated thumb, simple syndactyly of the fourth web, and brachyphalangism.

Other Features Other features of Apert syndrome are vertebral fusions, a “beaked” nose, cardiopulmonary abnormalities, and hyperseborrhea manifested as moderate to severe acne with unusual extension to the forearms. Drooling is also an issue, and the tracheal cartilages may form plates or a sleeve rather than rings, making intubation for procedures complex.

Genotype

Apert syndrome is autosomal dominant, with many cases being new mutations. It has a relatively narrow genotypic spectrum, with 98% of cases caused by one of two mutations in the FGFR2 IgI-IgII linker region, which leads to increased affinity and reduced specificity for the FGFR ligand, encouraging dimerization and increasing FGF signaling.¹⁸⁴ *FGFR2^{P253R}* constitutes 37% of identified mutations and is associated with a more severe limb phenotype; *FGFR2^{S252W}* is associated with cleft palate and constitutes the remaining 63%.¹⁸⁵

Developmental Implications A postmortem examination of one Apert syndrome patient showed premature fusion of the sphenoccipital synchondrosis and fusion of the vomer to the sphenoid and maxilla.¹⁷⁸ *FGFR2* is primarily expressed in midfacial membranous ossification, and

it has been shown that *FGFR2* gain-of-function promotes an increased number of cells to enter osteoblastic differentiation, leading to premature ossification.¹⁸⁶ The transgenic mouse model of Apert syndrome (*FGFR2*^{+/*S252W*}) demonstrated that individual cranial sutures exhibited different histologic changes; for example, the “metopic” suture exhibited increased proliferation and delayed osteoblastic differentiation, whereas in the sagittal suture osteogenic markers were increased. The basicranium had increased cartilage, and ectopic cartilage was seen in some organs, including the trachea and between calvarial bones.¹⁸⁷ This indicates that defects in chondrogenesis also play a role in Apert syndrome.

Much of the evidence suggests that Apert syndrome is a gain of *FGFR2* function that leads to an abnormal chondrocranial template, with premature ossification reducing rostrocaudal growth contributing to the midfacial hypoplasia.^{164,186,187} Membranous ossification of the calvarium is affected through abnormal osteoblastic proliferation and differentiation.

Crouzon Syndrome

Crouzon syndrome is the most common of the syndromic craniosynostoses. It is typically described as being similar to but less severe than Apert syndrome in appearance, but the craniofacial phenotype is different at all ages.¹⁸⁸ It constitutes 5% of all craniosynostoses, with a prevalence of 16.5 per 1 million¹⁸⁹ (Fig. 18-23).

Phenotype

Craniosynostosis With Chiari Malformation A variable pattern of craniosynostosis can occur in Crouzon syndrome patients, ranging from mild cases with little sutural involvement to more severe cases with multiple synostosis of a severe and progressive nature, including the cloverleaf skull.¹⁹⁰ In contrast to the skull of a patient with Apert syndrome, where the bregma synostoses by the formation of bony islands, a patient with Crouzon syndrome exhibits bicoronal synostosis that may progress to other sutures. The skull base synchondroses were found to be fused earlier than in Apert syndrome, and this together with the multiple craniosynostosis was suggested to

Fig. 18-23 Crouzon syndrome. **A** and **B**, Frontal and lateral views of an affected girl. **C**, Another patient with severe exorbitism, placing the globes at risk.

account for the increased intracranial pressure.¹⁹¹ Developmental delay is unusual, but headaches, seizures, and hydrocephalus are known to occur. Chiari malformation is found in up to 70% of Crouzon syndrome patients. It is postulated that fusion of the lambdoid suture together with cranial base synostosis produces alterations in the skull base, creating a small posterior fossa with herniation of the cerebellum into the cervical canal.¹⁹²

Exorbitism The lateral and inferior orbital rims are markedly hypoplastic, with the globe in a normal position relative to the cranial base. This is in contrast to the orbit of an Apert syndrome patient, in which the posterior orbital wall protrudes the globe.¹⁸¹ Optic atrophy is found in 20% of patients with Crouzon syndrome but is not characteristic of Apert syndrome patients.

Midfacial Hypoplasia Midfacial hypoplasia in Crouzon syndrome patients is less severe than in Apert syndrome patients but may have the same issues: respiratory compromise and obstructive sleep apnea resulting from the pharyngeal hypoplasia. One third of children with Crouzon syndrome are obligate mouth breathers because of their small nasopharynx. Cleft palate is rare, although a narrow palate occurs. There is dental crowding and a constricted arch as a consequence of maxillary hypoplasia with class III occlusion.

Other Features Other features include fusions between the C2-3 and C5-6 vertebrae, which occurs in up to 30% of Crouzon syndrome patients.¹⁹³ Hearing loss is common, with approximately one half of patients having conductive hearing loss.

Genotype

Crouzon syndrome is associated with *FGFR2*^{C342R} and *FGFR2*^{C342Y} mutations that lead to an unpaired cysteine residue, allowing ligand-independent cross-linking of the receptor dimers and constitutive activation.¹⁹⁴ These mutations have also been shown to cause Pfeiffer syndrome and Jackson-Weiss syndrome.¹⁹⁵

Pfeiffer Syndrome

Phenotype

Pfeiffer syndrome is an autosomal dominant disorder with incomplete penetrance and variable expressivity; it affects 1 in 100,000 live births.¹⁹⁶ The phenotypic spectrum is similar to that of Apert and Crouzon syndromes: a short anterior cranial base, midfacial hypoplasia with a class III occlusal relationship, an anterior open bite, a narrow high-arched palate, low-set ears, and conductive hearing loss. Pfeiffer syndrome is characterized by broad, medially deviated toes and thumbs, and radiohumeral synostosis with flexion deformity of the elbow. Cervical fusions, among other skeletal anomalies, have been reported.

Pfeiffer syndrome has been classified into three types by Cohen¹⁹⁷:

Type 1 Classic Pfeiffer: Isolated symmetrical coronal synostosis, broad thumbs and great toes, and incomplete syndactyly of the second web

Type 2 Cloverleaf skull: Severe midfacial hypoplasia and exorbitism, intracranial involvement with developmental delay, and ankylosis of the elbows

Type 3 Severe: Type 2, without the cloverleaf skull

Like the other facial dysostoses, Pfeiffer syndrome exhibits a brachycephalic calvarial morphology, and multisuture synostosis may cause more severe morphologies, including malignant exorbitism, midfacial hypoplasia, and airway issues.¹⁹⁸ Chiari malformation occurs in 50% of children with Pfeiffer syndrome, increasing to 100% in those with cloverleaf skull.¹⁹² Types 2 and 3 have a poor prognosis, with developmental delay and a limited lifespan.^{197,198} It has been suggested that a proactive approach with early tarsorrhaphies, aggressive airway management, and frequent screening for Chiari malformation may reduce mortality¹⁹⁹ (Fig. 18-24).

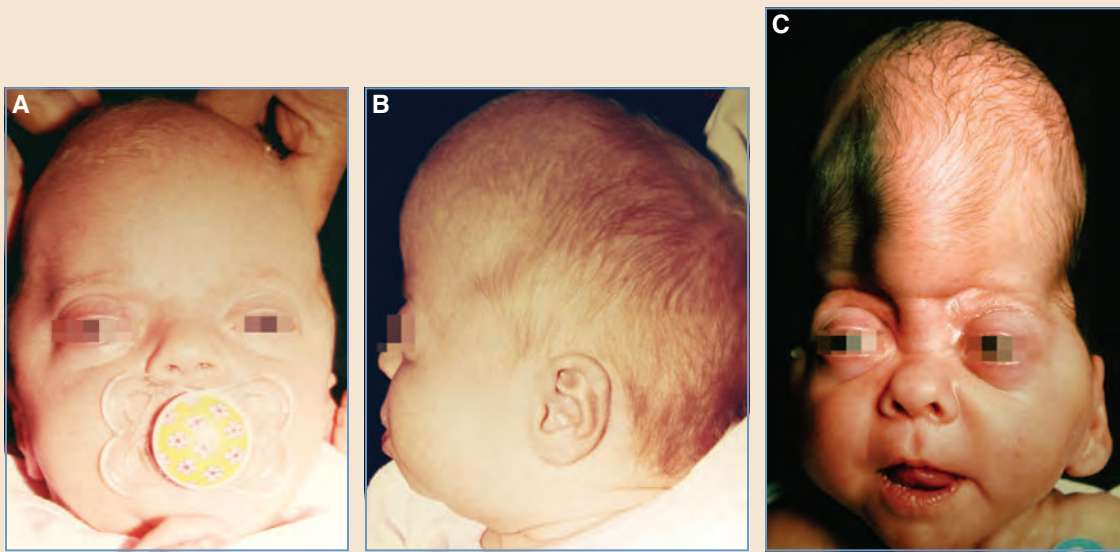

Fig. 18-24 Pfeiffer syndrome. **A** and **B**, This infant has type 1 Pfeiffer deformity with bilateral coronal synostosis. **C**, This infant has a type 2 deformity with pansynostosis and Kleeblattschädel deformity.

Genotype

The majority of patients with Pfeiffer syndrome have a mutation in *FGFR2*, but approximately 5% have a mutation in *FGFR1*.²⁰⁰ *FGFR1*^{P252R} results in the milder type 1 form of Pfeiffer syndrome, whereas types 2 and 3 are caused by *FGFR2* mutations only and may have abdominal anomalies such as prune belly syndrome and malrotations.²⁰¹ *FGFR2*^{C342Y} and *FGFR2*^{C342R} are responsible for cases of Crouzon and Pfeiffer syndromes, and *FGFR2*^{C342R} also results in Jackson-Weiss syndrome.²⁰² These mutations affect the IgIII loop and cause it to unfurl, allowing it to form heterodimers/homodimers and activate downstream signaling, irrespective of ligand activation. The reasons for the phenotypic differences in Pfeiffer syndrome patients remain to be explained but are likely to include modifying genes, variable ligand receptor activation, and epigenetic factors.

Jackson-Weiss Syndrome

Jackson-Weiss syndrome is a clinically distinct facial dysostosis characterized by bony anomalies of the feet, including a broad, short metatarsal and proximal phalanx of the great toe, abnormal tarsal bones, and tarsal/metatarsal coalitions. Involvement of the hands is generally not observed, but the similarity to Pfeiffer syndrome has been highlighted.¹⁹⁷

Developmental Implications

The underlying mechanism of Jackson-Weiss syndrome is the premature synostosis of the skull base and calvarial sutures. Clues to the mechanism come from the *FGFR2*^{C342Y} mouse, with a mutation equivalent to Crouzon and Pfeiffer syndromes.³ A child with Jackson-Weiss syndrome exhibits Crouzon features with invariant fusion of the coronal and partial fusion of the sagittal and lambdoid sutures. There is also progressive fusion of the synchondroses of the cranial base.²⁰³ Results suggest that *FGFR2* regulates the osteoblast proliferation and differentiation, resulting in enhanced osteogenesis. In the calvaria, more osteoprogenitor cell proliferation is observed. By contrast, the synchondroses show lower than normal chondrocyte proliferation; this is suggested to occur because the interaction of *FGFR2* with *FGFR3* during endochondral ossification demonstrates the different effects of the mutation on chondrocyte and osteoblast differentiation.

Muenke Syndrome

Nonsyndromic craniosynostosis was thought to be a sporadic phenomenon, but studies showed that approximately 30% of unicoronal synostosis had a genetic component.²⁰⁴ The most common of these was identified as an *FGFR3*^{P250R} mutation called *Muenke syndrome*, which affects approximately 10% of nonsyndromic unicoronal cases and 50% of nonsyndromic bicoronal cases.²⁰⁴ The equivalent mutation in *FGFR1* causes Pfeiffer syndrome and in *FGFR2* causes Apert syndrome.

There is significant phenotypic variability in patients with Muenke syndrome; however, *FGFR3*^{P250R} phenotypes lack the midfacial hypoplasia and have a variable craniosynostosis and limb involvement. They may have severe coronal synostosis (unilateral or bilateral), but the morphologic severity does not correlate with raised intracranial pressure.²⁰⁵ Learning difficulty in this group remains to be conclusively defined but may affect a minority of patients. In one series, all patients with Muenke syndrome had bilateral mild low- to mid-frequency sensorineural hearing loss and a 44% revision rate of frontoorbital remodeling as a result of recurrent deformity.²⁰⁴

Saethre-Chotzen Syndrome

Saethre-Chotzen syndrome is a heterogeneous autosomal dominant syndrome with variable expression, typically presenting with variable coronal synostosis, prominent crus helices, low frontal hairline, blepharoptosis, and incomplete simple syndactyly of the second web space. However, the presentation may include multisuture synostosis or no craniosynostosis, other limb anomalies, and ophthalmic issues such as lacrimal duct stenosis, strabismus, and pseudohypertelorism.²⁰⁶ Learning difficulties are uncommon in children with Saethre-Chotzen syndrome.²⁰⁷ The majority of patients have a mild dysmorphism; those with craniosynostosis are typically managed by frontoorbital remodeling, but the reoperation rates are comparable to those for Muenke *FGFR3* synostosis.

Although most patients with Saethre-Chotzen syndrome have a *TWIST* mutation, some patients with an overlapping phenotype have a mutation of *FGFR2* or *FGFR3*.²⁰⁷ The variability in the *TWIST1* mutation (more than 100 mutations) may account for the variable phenotype, but the nature of the mutation has not been shown to correlate with the severity of the craniosynostosis or the need for secondary surgery²⁰⁶ (Fig. 18-25).

Fig. 18-25 This 3-year-old child is one of four siblings who showed variable expression of Saethre-Chotzen syndrome inherited as an autosomal dominant trait from their affected father.

FGFR SYNDROME GENOTYPE-PHENOTYPE CORRELATIONS

We have discussed a family of related craniofacial dysplasias with similar phenotypes and a common underlying genetic origin. Nonetheless, a simple mutation-phenotype relationship does not exist; for example, the same mutation can lead to both Crouzon and Pfeiffer syndromes, and multiple mutations can cause the same single eponymous syndrome.^{200,202} This diversity arises from the nature of the FGF signaling pathway, which has great variability at a number of steps. Once the FGFR signaling system is established, growth depends on the balance between the proliferation of chondroprogenitor and osteoprogenitor cells with bone and cartilage maturation. Imbalances at different steps of the pathway lead to disparate phenotypic changes.

Whereas 98% of Apert syndrome cases are caused by two mutations in the *FGFR2* IgI-II linker region that confer increased ligand binding, Pfeiffer and Crouzon syndromes and related phenotypes show greater phenotypic heterogeneity and primarily arise from a wide range of mutations in the *FGFR2IIIc* region that creates a ligand-independent activation of the receptors. Pfeiffer syndrome may allow more promiscuous ligand binding but “normal” receptor dimerization and signaling, with a tighter phenotypic spectrum. Crouzon syndrome is ligand independent; the mutations may not only homodimerize but also heterodimerize, with *FGFR1* and *FGFR3* likely resulting in differing degrees of downstream signaling and a variable degree of ossification. Therefore IgIII mutations lead to heterodimerization, promoting cranial osteogenesis beyond the negatively autoregulated *FGFR2* domain.²⁰⁷ By doing so, the regions of the skull that express *FGFR1* and *FGFR3* may become recruited into the pathologic process, leading to multisuture synostosis.¹⁶⁴

Complicating this are the multiple splice variants of the IgIII loop that exhibit differential ligand binding and tissue specific expression. Superimposing all of this onto different genetic backgrounds and environmental factors explains why it is so hard to draw simple associations between mutations and phenotypes.

PRINCIPLES OF MANAGEMENT OF SYNDROMIC CRANIOFACIAL PATIENTS

All craniofacial patients should be managed within a multidisciplinary framework that includes a craniofacial surgeon, otorhinolaryngologist, ophthalmologist, orthodontic/pediatric dentist, speech and language therapist, dietician, psychologist, and pediatrician. The issues faced by individuals with different syndromes can be categorized systematically, because the management for each is similar, irrespective of the syndrome.

Airway Considerations

Airway issues for a syndromic craniofacial patient may be potentially catastrophic when presenting at delivery, or mild through severe when presenting soon after birth. Emergency airway management in the delivery suite is not considered here; subsequent management is important to facilitate feeding and prevent further complications.

In a neonate with respiratory difficulty, an initial task is to nurse the child in a side-to-side or prone position; nursing the child in a prone position allows a large tongue to sit forward in the mouth, clearing the hypopharynx. A large proportion of babies respond well to such conservative measures, and their airway control improves as they gain weight. If positioning does not improve the airway, then a nasopharyngeal airway (NPA) should be considered. An NPA is indicated if the obstruction is not alleviated by positioning, if the child's airway is obstructed when he or she is handled, or if there is increased airway difficulty with feeding. The NPA may be left in situ for a significant length of time, but if such an intervention is required long term, a tracheostomy should be considered. Before this, a thorough endoscopic evaluation of the airway should be performed to exclude multilevel obstruction, such as laryngomalacia, tracheomalacia, and bronchial stenosis; the level of obstruction will guide the intervention. Additionally, central causes, including hypotonia and central apneas, should be considered, and sleep studies may be of value. Choanal atresia is usually apparent early on, because neonates are obligate nasal breathers. The otolaryngologist plays a key role in evaluation and performing dilation (often repeated) or stenting of the obstruction. The hypoplastic nasopharynx in the facial dysostoses may be expanded by a LeFort III or monobloc osteotomy, but this is usually reserved for children with additional malignant exorbitism and raised intracranial pressure. Such procedures in very young children are associated with significant risk.

Feeding Considerations

A feeding assessment by an experienced practitioner is invaluable. One should be alert to signs of obstruction to an otherwise stable airway when feeding, such as slow feeding, falling asleep during feeding, and failure to gain weight. Conservative measures in cleft palate babies include the use of squeezey MAM bottles or Haberman feeders, with which the caregiver delivers the milk to the back of the throat. Continued poor intake mandates a nasogastric tube; the child may be re-evaluated periodically to try to return to oral intake. If long-term nasogastric feeding is required, consideration should be given to a feeding gastrostomy; this is more common in children with associated neurologic abnormalities.

Vision Considerations

Exposure of the globe can lead to blindness from corneal ulceration and even perforation. Impending exposure can be managed as for facial palsy patients, with lubrication using drops by day and ointment at night.^{208,209} If the limbus is observed during sleep and associated with ocular surface symptoms in the morning, then taping the eyelid shut at night is recommended. If this is not tolerated, consideration should be given to a temporary tarsorrhaphy; this is especially important in malignant exorbitism or repeated globe subluxations. The family can be shown how to reduce the globe after subluxation.

Visual assessment by an ophthalmologist is recommended in virtually all syndromic patients to identify further anomalies, institute early management of such conditions as dysconjugate gaze, and monitor for papilledema. Some centers use visually evoked potentials to monitor for increased intracranial pressure.

Hearing Considerations

In most countries a hearing test is available for newborns; suspicion of hearing issues should prompt further assessment. Auditory brainstem potentials can be performed with the infant under anesthetic in concert with another procedure; this gives information regarding sensorineural hearing. An ENT examination is important to identify and treat glue ear. Hearing tests in young children can be challenging, but they provide valuable information once a baseline is achieved. Provision of hearing aids is important for speech development; however, in instances of microtia, the decision to use a BAHA should be made as a team to avoid limitation of potential reconstructive options.

Speech Considerations

Speech therapists are vital members of the craniofacial team, performing regular speech assessments and therapy and providing advice to families as required. Typically an informal speech assessment is performed at 18 months of age, with a formal assessment at 3 years. Given the propensity for cleft palate in craniofacial patients, most of the management is focused on identifying and managing velopharyngeal insufficiency.

Psychology and Patient-Reported Outcome Measures

Facial difference has a huge impact on the patient and the family. The psychologist aims to explore these issues, providing advice and coping strategies tailored to the age and circumstances of the patient and family. Apart from surgical correction for functional reasons, much surgery is focused on “normalizing” the facial difference. It has become clear that the opinion of the patient and family regarding the quality of outcomes of treatment is important in guiding interventions. Recently, patient-reported outcome measures for facial aesthetics and cleft patients have been introduced. Such instruments are expected to become widespread in the future.

CONCLUSION

The combination of developmental biology and genetics heralds a new era for the diagnosis and classification of craniofacial differences. This chapter should equip the surgeon with a sufficient understanding of craniofacial development to understand the pathologic anatomy that will be encountered in the clinic. A systematic approach for the assessment and management of the child with craniofacial disorders is presented.

KEY POINTS

- Genes code for proteins, not anatomic structures or syndromes. Many genes have overlapping functions. Their action is modified by other genes and/or environmental factors: epigenetics.
- Genetic models exist for many human syndromes and provide insight into the mechanisms of disease.
- Craniofacial development is a stepwise process that consists of creating and then refining the morphology of the embryo.
- Midline facial development is intimately linked to brain development and underlies a spectrum of midfacial defects from holoprosencephaly to fronto-nasal dysplasias.
- Abnormal fusion of the facial processes is the cause of many typical and atypical facial clefts.
- Cleft palate may be a result of a failure of palatal growth, elevation, or fusion.
- Abnormal neural crest development leads to the branchial arch syndromes.
- Numerous signaling systems are involved in cranial suture morphogenesis and fusion.
- Defects in the cranial base underlie the facial dysostoses.
- Genotype-phenotype correlation in the FGFR-related facial dysostoses is complicated by their promiscuous signaling mechanism.
- Management of any craniofacial patient can be performed systematically by breaking issues down into airway, feeding, vision, hearing, and speech.

ACKNOWLEDGMENT

I want to acknowledge Mark Sisco and Bruce Bauer as authors of the previous version of the chapter, which is the foundation of this work.

Unilateral Cleft Lip Repair

William Y. Hoffman • David M. Fisher

left lip repairs have been documented for more than 3000 years, but only in the past half century has cleft care become more team oriented, with better and more predictable outcomes. To some extent, these surgical advances have corresponded to advances in pediatric and neonatal intensive care and anesthesia, but beyond, a gradual and incremental addition of technical improvements has resulted in much-improved appearance and function in patients with cleft lips.

The incidence of cleft lip and palate varies among different populations, from approximately 1 in 300 to 1 in 1000; approximately 50% have a cleft lip and palate, 30% cleft palate only, and 20% cleft lip only. Cleft lip is more common on the left side; the ratio of left/right/bilateral clefts is 6:3:1. Right-sided clefts are more often associated with syndromes.¹ A genetic or racial predilection for clefting has been noted; the incidence appears to be highest in Asian and Hispanic populations. A native tribe in Venezuela has an incidence of approximately 25%.² Numerous genetic syndromes are associated with clefts.

Although right-sided complete cleft lip may be more commonly associated with a syndrome than left-sided or bilateral cleft lip, cleft palate alone is still seen more commonly in association with syndromes than cleft lip plus or minus cleft palate. Regardless, children with cleft lip and palate should undergo genetic evaluation, because this may reveal more subtle associated anomalies and be predictive of possible recurrence rates. *Van der Woude syndrome* is an autosomal dominant condition in which clefts (with variable expression) are associated with lower lip “pits,” which are sinus tracts of the minor salivary glands.³

Cleft lip can be diagnosed prenatally by ultrasonography as early as week 20 of gestation. Newer, three-dimensional ultrasound imaging techniques have been developed, although not yet in widespread use, that provide a virtual image of the face; a number of studies have demonstrated the remarkable abilities of these studies to show congenital facial abnormalities^{4,5} (Fig. 19-1). In the future, if fetal surgery becomes more commonplace, it may be possible to repair cleft lips in utero with the advantage of the “scarless” healing that has been noted in the fetus.

Fig. 19-1 Three-dimensional ultrasound image of a fetus with a right cleft lip.

Fig. 19-2 Progression from a microform cleft lip to progressively greater incomplete clefts. **A** and **B**, Intact alveolar processes without a cleft palate. **C** and **D**, Greater involvement of the alveolus, with a complete cleft through the alveolus and palate shown in **D**. Greater nasal deformity is seen in **C** and **D**.

ANATOMY

Cleft lip results from a failure of merger of embryonic processes—the frontonasal process, which gives rise to the nose and the prolabium, and the maxillary processes on each side, which give rise to the rest of the upper lip on each side. The migration of neural crest cells from dorsal to ventral provides mesenchymal tissue, which is thought to supply the tissue to bridge the defects between the processes. The variable presentation of cleft lip is evidence that these events may be disrupted at various points in fetal development⁶⁻⁸ (Fig. 19-2).

Fig. 19-3 A, Displacement of the alveolus caused by the pull of the orbicularis muscles contributes to the nasal deformity and to tension on the cleft repair. B, Dental models at the time of cleft lip repair show the displaced alveolar processes.

Fig. 19-4 A typical cleft nasal deformity in a patient with a microform cleft lip.

Some surgeons have postulated that in a cleft lip all of the normal structures are present but merely displaced, whereas others maintain that there is an absolute deficiency of tissue. The variability is wide, and probably each is true to a different extent in each patient. Incomplete clefts will not necessarily have better outcomes; an incomplete cleft with a paucity of normal tissue may be more difficult to repair than a wide cleft with an adequate amount.

An alveolar cleft contributes significantly to a cleft lip and nasal deformity. The abnormal insertion of the orbicularis muscle exerts a distracting pull on the alveolar segments, particularly the medial portion, creating a step-off between the segments and inherent asymmetry of the nasal base and tension on the lip repair (Fig. 19-3). If this is not addressed preoperatively, the lip repair will require stretching tissue over the protrusive premaxillary segment, making it more difficult to obtain adequate length of the lip on the repaired side and creating additional tension on the lip repair. The elevators of the upper lip are generally normal but must be respected during surgery; wide undermining may disrupt their normal attachments and produce an asymmetrical smile.

The degree of cleft nasal deformity varies. Several factors contribute to nasal deformity—even in an incomplete cleft, some maxillary deficiency may be present in the area of the piriform aperture on the cleft side. The septum is typically deviated, with a convexity obstructing the cleft-side airway and the caudal septum presenting in the noncleft side. The ala stretch, and the dome of the lower lateral cartilage slumps. After a cleft lip is repaired, nasal obstruction may occur on the cleft side because of the septal deviation (Fig. 19-4).

PREOPERATIVE ASSESSMENT AND NONOPERATIVE TREATMENT

An assessment of the overall health of the child is paramount. This begins at the first visit, preferably in the first week of life. Pediatricians may not see many cleft patients in their practices. Particularly for children who have a cleft palate together with a cleft lip, it is imperative that a feeding specialist see the family to ensure that the infant is receiving adequate nutrition. A palatal cleft will reduce an infant's ability to suck, and most patients are not able to breast-feed.

Special bottles and nipples facilitate feeding infants with a cleft palate, and evaluation by a nurse or occupational therapist with expertise in this area is essential. These children may also have swallowing problems and reflux that are not necessarily associated with clefting.

As previously noted, a genetic evaluation should be performed before lip repair, with a particular emphasis on other affected organ systems. Developmental delay is not generally a reason to delay a lip repair, unless a patient has significant hypotonia and recovery from anesthesia is a concern. Respiratory and cardiac problems would necessitate some delay in lip repair.

Most children with complete clefts benefit from some sort of manipulation of the alveolar segments before cleft lip repair. A number of centers use molding plates to move the segments into a more anatomic relationship; the addition of a prong to mold and stretch the nasal cartilage is called *nasoalveolar molding*.^{9,10} This has the advantages of reducing tension on the lip repair and greatly reducing the cleft nasal deformity (Fig. 19-5). For patients whose alveolar segments are in close contact, gingivoperiosteoplasty has been proposed as a method to reduce the need for later bone grafting and to maintain the maxillary segments in position after the molding process. The disadvantages of this procedure are the labor involved and the need for frequent office visits, which may be a problem when patients have to travel a long distance to be seen by a cleft team. Long-term outcome studies are in preliminary stages but appear favorable; however, at least one study has suggested that the nasal improvement from nasoalveolar molding tends to regress with time after lip repair.¹¹

Fig. 19-5 A, A unilateral cleft lip before nasoalveolar molding. B, The same patient after nasoalveolar molding. (Courtesy of Barry Grayson, DDS, and Court Cutting, MD.)

Fig. 19-6 Presurgical taping is a low-cost method of closing an alveolar gap, although with less accuracy than nasoalveolar molding.

Other alternatives to nasoalveolar molding include external pressure, either with elastic devices or more simply with tape pulled across the cleft tightly enough to reduce the alveolar gap (Fig. 19-6). The advantages are simplicity and low cost, without the need for close follow-up; however, the gap does not close to the same extent that can be achieved with molding, and thus gingivoperiosteoplasty is not generally possible.¹² Whether this is an important factor will only be determined by prospective outcome studies of specific treatment protocols.

Lip adhesion is another technique that has been applied to narrow alveolar gaps. In contrast to nasoalveolar molding or taping, this is a surgical procedure that basically converts a complete cleft to an incomplete cleft by suturing relatively small subcutaneous flaps together.¹³ The disadvantages of this technique include scar tissue in the area of the definitive cleft lip repair and the risk of dehiscence of the small flaps, which is higher with wide clefts where the need for some sort of control of the alveolar gap is greatest.

SURGICAL OPTIONS

Many surgical methods for cleft lip repair have been described, and new modifications are reported on a regular basis. Early repairs simply pared the cleft margins and sutured them together¹⁴ (Fig. 19-7). A straight-line repair is used for only the most minimal of clefts; otherwise, scar contracture will shorten the lip and to some extent re-create the deformity. All other lip repairs have in common the use of local flaps to elongate the lip at the high point of Cupid's bow and to disrupt the forces of scar contraction. In the early part of the twentieth century, LeMesurier¹⁵ described the use of quadrilateral flaps for this purpose, but these techniques required discarding a substantial amount of lip tissue and disrupted the normal philtral anatomy (Fig. 19-8).

Fig. 19-7 Straight-line repair.

Fig. 19-8 LeMesurier repair.

A triangular lip repair (Tennison-Randall)^{16,17} changed the right-angle flaps of a quadrilateral repair to a modified form of Z-plasty just above the vermilion border (Fig. 19-9). An *inferior triangle repair* is a Z-plasty in which the middle limb of the A is shared by the incised cleft margins. Tennison¹⁶ used a bent wire as a stencil to produce a zigzag scar with equal limbs. Randall¹⁷ used calipers and simple mathematics. He created the required length while reducing the size of the inferior triangle. In this repair, the total lip height of the noncleft side is measured from a reference point in the nostril sill to the noncleft-side peak of Cupid's bow. The greater lip height is measured on the cleft side from the proposed medial point of closure at the height of the lip in the nostril sill (symmetrical with the reference point in the noncleft-side nostril sill) to the cleft-side peak of Cupid's bow. The difference between the total lip height and the greater lip height is the approximate height of the lesser height, the base width of the inferior triangle required to level Cupid's bow (see Fig. 19-13). An inferior triangle repair has several advantages. The nostril sill is closed by simple side-to-side approximation of medial and lateral nostril sill elements, and scarring at the base of the nose is minimal. Lip length can be obtained even when the medial lip

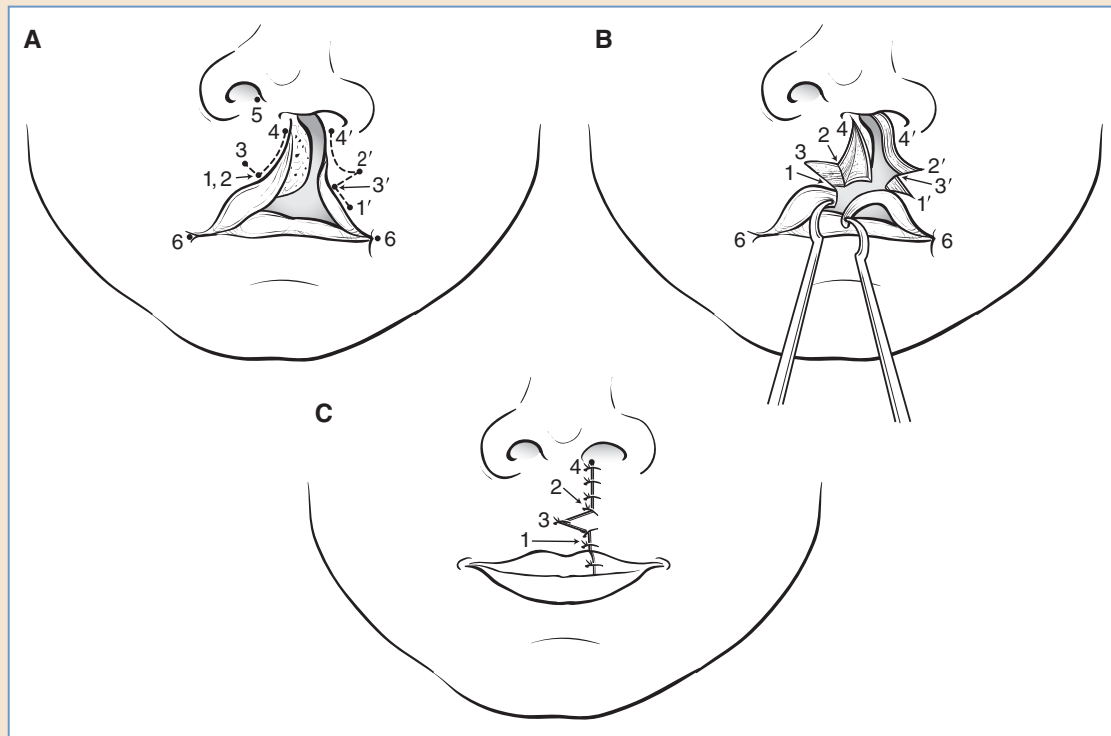

Fig. 19-9 Tennison repair. **A** and **B**, Markings for a triangular (Tennison) repair. Numbers 1 through 4 will be joined to their counterparts in the repair. **C**, Length is increased from the Z-plasty placed in the lower part of the philtrum.

height is very short. When the lateral lip height is short, often the case in patients with a complete cleft, lateral lip height can be added without compromising *Noordhoff's point* (identified on the vermilion-cutaneous junction, where the cutaneous roll and vermilion-mucosal junction lines start to converge medially).¹⁸ The disadvantage is a nonanatomic zigzag scar. Secondary revisions may be challenging, because the Z-plasty is in the middle of the lip.

In Millard's initial rotation-advancement repair,¹⁹ a curvilinear (rotation) incision is made in the medial lip element. The rotation incision mirrors the noncleft-side philtral column in its lower half. The incision then skirts along the lip-columellar crease and approaches but should not cross the noncleft-side philtral column. The incision allows caudal rotation of the cleft-side peak of Cupid's bow. The resultant defect is filled with a large, triangular (advancement) flap from the lateral lip element. Prolabial skin lateral to the rotation incision forms a C flap. It is rotated laterally and contributes to closure of the nostril sill (Fig. 19-10).

Millard²⁰ observed that the rotation of Cupid's bow was often inadequate and introduced a backcut extending from the most cranial extreme of the rotation incision down the lip just medial to the noncleft-side philtral column. The backcut is extended caudally as much as needed to level Cupid's bow. It leaves a quadrilateral-shaped defect that is filled by the C flap. The C flap can be advanced to elongate the columella on the cleft side.

The main advantage of a rotation-advancement over previously described repairs is that it preserves Cupid's bow and the philtral dimple. At least in the lower half of the lip, the scar mir-

Fig. 19-10 Millard repair. Flaps are cut and ready for transposition; the Z-plasty is moved under the nasal sill. **A**, Advancement flap incisions are marked along the edge and around the alar base. A C flap is present under the columella. **B**, Advancement of the C flap into the columella. In Millard's original description, lateral placement of the C flap created a Z-plasty of the vertical scar that placed the tension just under the nasal sill and columella, creating flatness where it is normally seen and allowing a more natural pout of the lip at the vermilion border.

rors the noncleft-side philtral column. Many surgeons like the so-called cut-as-you-go execution of the repair.

Rotation-advancement has several drawbacks. The scar is not the anatomic mirror image of the philtral column in the upper half of the lip. The repair introduces excessive scar at the base of the nose (columellar base, nostril sill, and alar crease). When the C flap is used to fill the backcut and support the columella, it no longer can be used to the same extent to close the nostril sill. Nostril stenosis can result. The medial and lateral elements of the nostril sill are present in the unrepaired state. Augmenting the nostril sill closure with skin from the lip is not needed, and the C flap only interrupts the nostril sill roll. A long incision around the base of the nose is unnecessary and produces an obvious scar. Many surgeons have abandoned this element of the repair, deeming the alar crease incision unnecessary. The length of the cleft marginal incision of the lateral lip must be sufficiently long to meet with the full length of the rotation incision. When the lateral lip element is vertically short (as in most complete clefts), surgeons will need to extend the incision beyond Noordhoff's point. The transverse length of the lateral lip, usually already short, is thus further compromised to obtain vertical height.

Mohler²¹ altered the markings of the rotation-advancement repair to result in a scar that is more symmetrical with the noncleft-side philtral column. The change was made by straightening the curve of the rotation incision and extending it into the columella. The backcut was turned 90 degrees and ended at the lip-columellar crease. The resultant transverse limb of the repair is elevated to the lip-nose junction, marking an improvement over the original version. Mohler stated that the columella seems to be a rather silent donor site; however, Noordhoff¹⁸ warned that when the columella is narrow, a Mohler repair is contraindicated. The advantage of the repair over Millard's rotation-advancement is a more anatomically positioned scar. However, it shares with all rotation-advancement repairs a necessary compromise of transverse lateral lip length when the lateral lip is vertically short.

Noordhoff¹⁸ modified Millard's original repair. In this modification, an alar crease incision is not used. When rotation of Cupid's bow is inadequate, a small opening cut is made above the cutaneous roll above the cleft-side peak of Cupid's bow. A small triangular flap from the lateral lip is introduced into this defect. This triangle is inconspicuous and provides tension in the repair in the ideal position, above the roll, which accentuates the pout of the lip. Noordhoff also stressed the importance of achieving balance in the red lip and a level vermilion-mucosal junction (red line). Vermilion is almost always deficient in height below the cleft-side half of Cupid's bow. Here, Noordhoff augments the deficiency with a laterally based vermilion flap from the lateral lip.

I (D.M.F.) described the *anatomic subunit approximation technique*,²² which aims to produce a cutaneous scar along the seams of anatomic subunits. It is a modification of the Rose-Thompson^{23,24} repairs and usually incorporates elements of a modified inferior triangle repair. It offers several advantages over previously described techniques. (See Surgical Technique: Fisher Anatomic Subunit Approximation for a more detailed discussion.)

Management of the alveolar cleft was mentioned previously. If the alveolar segments can be brought into proximity, a gingivoperiosteal flap can be elevated and closed in continuity with the lip repair. The effects on subsequent maxillary growth and dental eruption patterns are concerns with this procedure. Follow-up of small cohorts of patients has shown that bony union of the alveolus occurs in most patients, and that approximately two thirds of the patients do not require subsequent bone grafting.²⁵ Growth appears to be similar to that in patients with an unrepaired alveolus. A small number of centers place a rib graft in the alveolar gap in the first year of life and claim that their patients have no growth retardation.²⁶ A comparative study showed some deficiency in maxillary growth in patients undergoing early bone graft, compared with gingivoperiosteoplasty or no early alveolar closure.²⁷

The level of undermining of the medial and lateral flaps during repair has been a topic of some discussion. The traditional method of repair has used undermining in the soft tissue to release the orbicularis muscle, leaving the periosteum intact. Delaire et al²⁸ and more recently Carstens²⁹ have advocated subperiosteal undermining with the argument that it restores normal anatomy more naturally and follows embryonic field anatomy. Although this is theoretically appealing, there are no long-term data or comparative studies on this issue. Older animal studies suggested that subperiosteal dissection may result in greater restriction of maxillary growth. Whether active or passive appliances are used to aid in approximation of the alveolar segments before lip repair, the need for extensive undermining of any kind is minimized, and the risk of growth restriction is minimized to the extent possible.

As lip repair has become more predictable, the nasal deformity is recognized as a persistent stigmata of cleft patients. McComb and Coghlan³⁰ first popularized correction of the cleft nasal deformity at the time of the initial lip repair by demonstrating long-term outcomes without deleterious effects on nasal growth. Preoperative nasoalveolar molding may possibly supplant surgical nasal correction, but some patients will benefit from some correction of the nose at the time of lip repair.^{25,31}

SURGICAL TECHNIQUE: HOFFMAN

Dedicated pediatric anesthesiologists are critical. Anesthesia is induced by mask and intravenous access is established. No antibiotics are needed for a soft tissue operation. An oral right-angle endotracheal tube is ideal for this procedure and is secured in the midline of the lower lip and chin. An oral gauze pack maintains the tube in a stable position, reduces leakage of gas from the uncuffed tube, and prevents blood from entering the posterior airway. The eyes are protected with clear plastic adhesive dressings, and the entire face is prepared with povidone-iodine solution.

The lip is marked with brilliant green dye, which is alcohol based and is useful for making fine lines; a fine skin pen can be used as well. The marking must be made before infiltration of a local anesthetic. Once the local anesthetic is injected, the lip is distorted, making evaluation of the anatomy more difficult. Visualizing a normal lip and constantly referring to the opposite side to guide the repair help to ensure symmetry, which is essential for a good outcome.

A rotation flap is marked first. The new high point of Cupid's bow on the cleft side is determined by first marking the midline and then the existing high point on the normal side; this distance is matched on the cleft side. This point on the vermilion border is tattooed using a 27-gauge needle and brilliant green dye. Surgeons tend to make this point too far up along the cleft margin, which is more lateral. This will result in greater difficulty in establishing adequate rotation downward and will produce a prolabium that is too wide. The rotation flap curves from the tattoo mark on the vermilion border upward to the base of the columella. The upper portion of the rotation flap should not cross the opposite philtral column; if necessary, a backcut along this line can be made for additional rotation. The remaining cutaneous portion of the medial lip, between the rotation flap and the mucosa, becomes the C flap. The mucosa is cut directly down from the vermilion border at the high point of Cupid's bow, leaving a base at the premaxilla. No mucosa should be included in the C flap, because this will cause the scar to have a permanent pink color.

The advancement flap results from the separation of the mucosa and the skin on the lateral lip segment. Many methods are available for determining the point along the vermilion border where the lateral and medial lip elements should meet. The greatest fullness of the mucosa has been advocated, as well as a point where the white roll becomes well defined. In general, because the height of the advancement flap from the vermilion border to the alar base will determine the lip height, I (W.Y.H.) prefer to measure the corresponding height on the contralateral side and transpose this measurement to the cleft side. This is another example of the principle of using the normal side as a reference. As on the medial side, the vermilion border is tattooed to mark this spot once it has been determined. As mentioned previously, the mucosa should not be included in the cutaneous flap; doing so permanently discolors the scar (Fig. 19-11).

The lip is infiltrated with lidocaine 0.5% and epinephrine 1:200,000. This mixture has 5 mg of lidocaine and 5 μ g of epinephrine per milliliter of solution, and if no more than 1 ml/kg is used, the dosage will be well within acceptable limits. Ideally, a full 7 minutes is allowed for the hemostatic effect of the epinephrine, which will be apparent from the blanching of the soft tissue.

A rotation flap is incised first, all the way through the vermilion border down to the premaxilla. A C flap is cut, and a medial mucosal flap is elevated with the submucosal glands down to the premaxilla to expose the underlying orbicularis oris muscle. The C flap is dissected upward superficial to the orbicularis muscle, which is just below the dermis. The dissection of the orbicularis muscle is circumferential but does not extend farther than the midline of the prolabium to preserve the natural philtral dimple. The plane of dissection is just below the dermis in the cutaneous portion, but is somewhat deeper in the mucosal portion, preserving the submucosal glands with the mucosal flaps. The muscle is released from the base of the columella. This allows downward rotation of the muscle and the cutaneous flap. Last, the muscle is freed from the premaxilla itself, staying above the periosteum.

The advancement flap is incised in a similar manner; again, the mucosal flap is rotated downward and based on the maxillary attachment, and the orbicularis muscle is dissected circumferentially. Unlike Millard's initial description,¹⁹ no incision is made around the alar base; this is unnecessary and creates a difficult scar with permanent effacement of the alar-cheek junction. A small tongue of dry mucosa is maintained on the advancement flap, because usually the central prolabium contains an insufficient amount of dry mucosa. Once the mucosal flap is dissected down to the periosteum, the advancement flap is released along the vestibule, extending this incision

Fig. 19-11 A, A complete cleft lip before markings are made. A right-angle endotracheal tube is secured to the lower lip. B, Markings are made with brilliant green dye. C, The height of the lip is measured on the uninvolved side. D, The height is matched to determine the length of the advancement flap on the lateral lip element.

approximately 1.5 cm and then dissecting above the periosteum on the face of the maxilla. This is done entirely with blunt dissection; a finger on the inferior orbital rim will protect the eye.

A McComb nasal correction is started before closure.³⁰ First, the nose is released from the piriform aperture. The dissection on the face of the maxilla allows the scissors to be placed on the piriform aperture with one edge on the inside of the nose. The lateral nasal wall is sharply divided just above the inferior turbinate. A small tenotomy scissors is used to dissect over the alar cartilage on the cleft side of the nose, entering below the C flap in the midline and from the alar base laterally. This dissection is carried over the domes of both alar cartilages and up onto the dorsum. Releasing the lateral crus of the alar cartilage on the cleft side all the way down to the alar rim is critical (Fig. 19-11, E through G).

The lip closure progresses from inside to outside. The lateral mucosal flap is transposed 90 degrees to close the defect on the nasal sidewall. Usually, some of the length of this flap must be trimmed to fit well. The medial mucosal flap is turned over and sutured to the medial portion of the lateral flap. This provides lining for the floor of the nose and the vestibule of the advancement flap as it is brought across the cleft (Fig. 19-11, H). The nasal sidewall is now closed to the newly created floor of the nose, suturing to a small portion of the lateral mucosal flap and then to the medial mucosal flap, with the corner of the nasal cut coming into the defect left by the top of the C flap. Comparison with the opposite side of the nose provides a template to establish

Fig. 19-11, cont'd E, The nose has been freed from the piriform aperture, together with the advancement flap. F, Freeing the alar cartilage from the overlying skin from the lateral incision. G, The alar cartilage is further released from the midline. H, The nasal floor is closed with the lateral and medial mucosal flaps sutured to each other across the alveolar cleft. I, A triangular lip flap is performed just above the vermilion border to lengthen the repair.

symmetry. The vestibular incision is closed, placing medial traction on the advancement flap to determine placement of the sutures.

The alar base is anchored to the base of the columella using an absorbable monofilament suture. This has the dual function of taking tension off the nasal floor repair and bringing the tilted columella into the midline. The orbicularis muscle is also closed with absorbable monofilament suture; this is a critical repair, because the integrity of the muscle is linked to subsequent lip growth and to normal function. Rotating the medial muscle downward is essential; these sutures should take tension off the lip repair, and the initial tattoos on the vermilion border should be aligned at this point.

The lip closure begins by rotating the C flap medially between the base of the columella and the rotation flap. This takes some of the tension off the advancement flap, adds to the height of the repaired side of the lip, and creates better symmetry of the columella. If the rotation and advancement flaps overlap, minimal trimming can be done; the curve of the final closure should be a mirror image of the opposite philtral column as much as possible. Skin is closed with 6-0 fast-absorbing catgut; occasionally, two or three dermal sutures of 5-0 material are placed to relieve tension, but usually this is achieved by the muscle repair. After the C flap is closed, the first suture is placed through the two tattoos at the white roll.

The length of the repaired lip must be carefully assessed. If the repair has adequate length, the mucosal closure should be completed; otherwise, a triangular lip flap, as described by Noordhoff, should be used. This involves a 1 to 1.5 mm incision just above the vermilion border

Fig. 19-11, cont'd **J**, A flap of dry vermilion (*) is preserved from the lateral lip element, which will be inserted into the medial lip to improve the balance of wet and dry mucosa. **K**, The completed lip repair with bolster sutures placed. The C flap is positioned in the nasal sill in this patient, although it is often rotated medially under the columella.

on the medial side and a corresponding small flap to fill the defect from the lateral side. Essentially, it is a tiny Z-plasty placed just above the vermilion border (Fig. 19-11, *I*). The only contraindication to using this flap is a lip that is so short that the surgeon thinks a revision will be required once the child has grown. In these cases, surgeons may choose not to use a triangular flap at the initial lip repair and to wait until the revision.

The mucosal repair is equally important. The alignment of the dry vermilion and wet mucosa, the so-called red line, is assessed first. As noted previously, a paucity of vermilion in the central part of the lip is typical. By preserving a tongue of vermilion with the lateral advancement flap, this can be inserted into an incision made along the vermilion medially (Fig. 19-11, *J*). Any excess below this is trimmed, and a 5 mm Z-plasty is placed in the wet mucosa to prevent notching of the closure.

The nasal correction is completed after the lip is closed. Two bolster sutures are placed in the nose to create a new relationship between the alar cartilage and the overlying skin. The first is placed in the dome of the alar cartilage and brought out percutaneously at the opposite side of the dorsum to pull the alar dome up and medially. The second is a percutaneous suture placed across the fold of the lateral crus that inevitably occurs, exiting in the lobular crease of the nose. Both of these sutures are polypropylene and are applied with pieces of 8 Fr rubber catheter to bolster the skin against erosion. The sutures are tied relatively loosely, and the tension of the sutures on the rubber is used to keep the repair in place. Generally, this appears overcorrected in the operating room and often appears undercorrected later (Fig. 19-11, *K*).

Postoperative Care

Bacitracin ointment is placed on the suture line. We prefer to place a Logan bow to relieve tension and to protect the lip repair for the first few days; this is not replaced once the tape loosens. Others think that this device is not needed to protect the lip repair. Arm restraints are used for approximately 10 days. Most of our patients stay in the hospital overnight, because they come from too great a distance to drive home, but local patients may be discharged the same day if they are doing well. No feeding restrictions are necessary, and whatever method of feeding was used preoperatively is continued after surgery.

Patients are seen in the office 4 to 5 days postoperatively. The fast-absorbing catgut sutures are absorbed in this short time, thus preventing crosshatch marks and the need for suture removal. The two nasal sutures and bolsters are removed.

Outcomes and Complications

Complications of cleft lip surgery are rare. Although opinions vary between surgeons, neither one of us gives patients prophylactic antibiotics for cleft lip repairs. Out of nearly 1000 cleft lip repairs, none has had an infection, and only one had a dehiscence. A small number of patients developed inclusion cysts, and no hematomas occurred.

Typically, scar hypertrophy begins after 3 to 4 weeks, and parents are informed about this in advance. Although taping or massage may improve scars, it can be difficult to perform in an infant. Generally, scar hypertrophy improves on its own. If the lip had adequate length at the end of the procedure, it may appear a little short as the scar hypertrophies, but it usually returns to a symmetrical length after several months (Fig. 19-12).

The goal of a unilateral cleft lip repair should be a normal appearance with symmetry of the lip and nose. Minimal or no revision of the lip should be required. Usually, something can be found to be lacking, but it should be possible to delay revision until bone grafting is performed or ideally until the patient is a teenager. The most common problem is redundancy of the *mu-cosa* on the cleft side, which results from movement of the alveolar shelves after the lip repair.

If a significant deformity persists after healing is completed, revision should be undertaken before the child is of school age for his or her psychological benefit. Such an early revision is required in less than 25% of our patients.

Fig. 19-12 A, Hypertrophic scarring 2 months after a cleft lip repair. B, Improvement in the scar and lip length 5 months postoperatively. C, Marked improvement 1 year postoperatively.

A nasal deformity is a different issue. The septum is deviated to the side of the cleft posterosuperiorly and toward the normal side caudally, and the dorsum is deviated away from the side of the cleft in most cases; the long-term results of nasoalveolar molding are not yet known in this regard. Even after a McComb procedure,³⁰ most if not all children with unilateral clefts require a septorhinoplasty in their teens; generally, earlier surgery on the septum may impede growth of the maxilla. Alternatively, the primary nasal correction described previously will markedly improve symmetry over no repair and will be sufficient for most children until they are teenagers.

Secondary surgery on the lip and nose is best delayed until the underlying bony and dental structures are as symmetrical as possible. Generally, this is after the first and second phases of orthodontics are completed, with alignment of the alveolar segments, bone grafting, and alignment of the permanent teeth into ideal occlusion. LeFort I maxillary advancement, if needed, should also be done before final lip and nose surgery.

SURGICAL TECHNIQUE: FISHER ANATOMIC SUBUNIT APPROXIMATION

Incisions for the anatomic subunit approximation technique²² cross the cutaneous rolls of the lip elements in a perpendicular fashion (Fig. 19-13). The incision on the medial cleft side then ascends from a point above the cutaneous roll to mirror the noncleft philtral column. An angle is formed between the incision line crossing the medial lip element roll and the philtral column

Fig. 19-13 Presurgical markings and measurements. The total lip height (*a*) and the greater lip height (*b*) are each measured from points above the roll to the base of the columella. The lesser lip height (*c*) (base width of the small, inferior triangle) is equal to the total lip height minus the greater lip height minus 1 mm. The 1 mm accounts for the Rose-Thompson lengthening that occurs as the angled incision lines approximate in the vertical.

$$\begin{aligned}\text{Lesser lip height} &= \text{Total lip height} - \text{Greater lip height} - 1 \text{ mm} \\ \text{Lesser lip} &= \text{Base width of the small inferior triangle}\end{aligned}$$

incision. This angle will open to create a straight line and lengthen the lip by approximately 1 mm. At the height of the lip, the incision line curves superolaterally, just below the lip-columellar crease and thus preserving it, to the medial point of closure in the nostril sill. Lip length is gained by two mechanisms: first, a Rose-Thompson^{23,24} effect as angled lines straighten on approximation (which accounts for approximately 1 mm of lengthening) and second, if required, a small inferior triangle from the lateral lip element, which is positioned just superior to the cutaneous roll. The lengthening obtained by following the Rose-Thompson principle significantly reduces the size of the inferior triangle that would otherwise be required had a traditional inferior triangle repair been performed. The technique also uses a Noordhoff lateral vermilion triangle flap (C flap) to augment the deficient vermilion height of the medial lip element on the cleft side.

This technique has many advantages over the inferior triangle and rotation-advancement repairs. In contrast to the rotation-advancement techniques,^{20,21,32} scarring at the base of the nose is minimal. The cutaneous scar is positioned along the seams of anatomic subunits with the exception of, when required, a small triangle above the cutaneous roll. For several reasons, this is the preferred position of an inferior triangle^{20,21,32}:

- Tension is ideally positioned above the roll and accentuates the pout of the lip.
- Continuity of the cutaneous roll is achieved by side-to-side approximation of the roll elements, simplifying the light reflex off the roll.
- It allows the creation of a lengthening angle above the roll.
- The roll does not need to be augmented—doing so will create a stairstep of the non-hair-bearing roll and hair-bearing skin junction. The repair preserves the lateral lip element on the cleft side.
- In common with the inferior triangle repair, lateral lip transverse length need not be compromised to gain vertical height, a commonly practiced compromise when performing a rotation-advancement-type repair.

The lateral lip element is almost always short in its transverse dimension, compared with the noncleft side. As commonly seen in complete clefts, the vertical height of the lateral lip is also short.^{33,34} The practice of moving the base of the incision laterally to gain vertical height is a compromise that is often required when performing a rotation-advancement repair, but is not required with the anatomic subunit approximation technique.

The cleft-side Cupid's bow peak and philtral column height are marked equidistant from the midline relative to the corresponding noncleft-side markings. The noncleft-side Cupid's bow peak is not marked at the highest point of the curve of the lip, but rather where the straight portion of the noncleft-side half bow meets the convexity of the lateral lip element (Fig. 19-14). No such convexity exists on the cleft side of the medial lip element. The corresponding convexity on the cleft side will come from the lateral lip element lateral to Noordhoff's point.

Points are marked above each bow peak just over the cutaneous roll at points above the lines perpendicular to the vermilion-cutaneous junction. The medial lip cleft-side philtral column incision (equivalent to the greater lip height) will ascend from the point above the roll to the height of the lip just below the lip-columellar crease. The incision line then traverses from the height of the philtral column incision (greater height incision) superolaterally to the medial point of closure in the nostril sill (this length is called the *third height*). From the point above the roll, the incision line continues caudally perpendicular to the roll through the bow peak and vermilion and across the free border of the lip into the mucosa.

The point of origin of the opening incision for the medial lip backcut (if indicated) is initiated just above the cutaneous roll. The opening incision is drawn perpendicular to the greater height incision.

The medial and lateral points of closure within the nostril sill are not distinct anatomic points and thus are the hardest points to define in this repair. The medial point of closure in the nostril

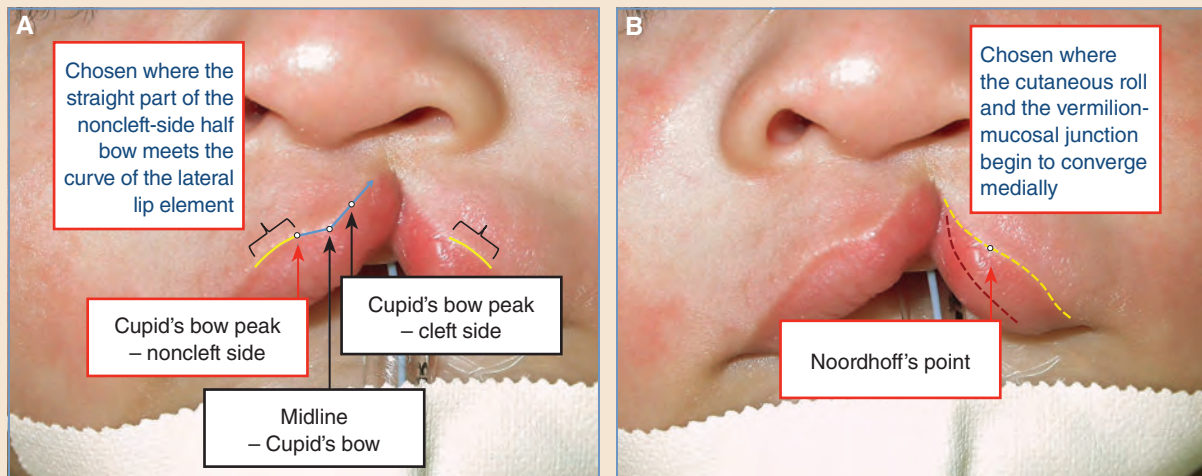

Fig. 19-14 A, The noncleft-side Cupid's bow peak is not marked at the highest point of the curve of the lip. It is marked where the straight portion of the noncleft-side half bow (*blue line*) meets the convexity of the lateral lip element (*yellow line*). There is no such convexity on the cleft side of the medial lip element. This curve of the bow on the cleft side will come from the lateral lip element lateral to Noordhoff's point, shown in B. The cleft-side peak of Cupid's bow is positioned on the vermillion-cutaneous junction on the cleft side of the medial lip element equidistant from the midline of the bow. B, Noordhoff's point is identified on the vermillion-cutaneous junction (*yellow dashed line*) where the cutaneous roll and the vermillion-mucosal junction lines start to converge medially. The upward convexity of the lateral lip element lateral to Noordhoff's point should be preserved.

sill is positioned lateral to the curve of the lip-columellar crease. It will be positioned more medially in complete cases and more laterally in incomplete cases. This will allow surgeons to adjust the length of the third height and therefore use less lateral lip height in complete cleft patients with vertical height deficiency or more of the lateral lip height in patients with incomplete clefts and excess vertical height. The lateral point of closure in the nostril sill is chosen on the lateral lip element, relative to the medial point of closure in the nostril sill. Approximation of these two points should accomplish two goals: the nares are of equal circumference and the alar bases are symmetrical from the anterior view. Gentle manipulation of the medial and lateral lip elements should confirm acceptable positioning of these points. In complete clefts in which the lateral lip is so tethered that the medial and lateral lip elements cannot be brought together, releasing the lateral lip element before marking the lip is advised.

Calipers are used to measure the *total lip height*, defined as the height of the noncleft-side philtral column from a point above the roll to a point just below the lip-columellar crease, and the *greater lip height*, defined as the height of the cleft-side philtral column incision from a point above the roll to a point just below the lip-columellar crease and positioned along a line that mirrors the noncleft-side philtral column (see Fig. 19-13). The total lip height is measured with the lip at rest. The greater lip height is measured with gentle downward traction on the lip to unfurl the medial lip. The lesser lip height (equivalent to the base width of the small inferior triangle) is equal to the total lip height minus the greater lip height minus 1 mm. The 1 mm accounts for the approximate length achieved by the Rose-Thompson principle. If an inferior triangle is required, the backcut for the opening incision is drawn perpendicular to the greater lip height incision and of a length equal to the lesser lip height (the inferior triangle is equilateral). Rotation of the bow is achieved by the combination of the backcut and the Rose-Thompson effect^{23,24} (as the angled lines straighten). The lesser lip height is usually 1 to 1.5 mm and never exceeds 2 mm.

For minor-form incomplete clefts, an inferior triangle is often not necessary. The backcut is made perpendicular to the greater height incision and not parallel to the cutaneous roll, which would produce a flattening of Cupid's bow when the backcut is opened. The perpendicular backcut preserves tissue above the roll and thus better conserves the curve of Cupid's bow.

The base of the cutaneous incision on the lateral lip element is marked according to the recommendations of Noordhoff. Noordhoff's point is marked along the vermilion-cutaneous junction at the point where the cutaneous roll and red line begin to converge medially. The natural upward convexity of the cutaneous roll lateral to Noordhoff's point is ideally suited for reconstruction of the cleft-side curve of the bow. A point is marked just above the cutaneous roll at a point above Noordhoff's point, along a line perpendicular to the vermilion-cutaneous junction. Between the lateral point of closure in the nostril sill and the point above the roll, three lengths must be accommodated: the greater lip height, the lesser lip height, and the third height (corresponding in length to the line connecting the height of the cleft-side philtral column and the medial point of closure in the nostril sill). This is readily achieved by placing the greater-lip-height caliper on the lateral lip element so that its lower tip lies the lesser-lip-height distance away from the point above the roll, and its upper tip lies the third-height distance from lateral point of closure in the nostril sill.

In complete clefts, with a short vertical height to the lateral lip element, the angle of the greater lip height incision on the lateral lip will be more horizontal and, in extreme cases, may be confluent with the upper limb incision of the inferior triangle (Fig. 19-15, *A*). It is also helpful in patients with a lateral lip element vertical height deficiency to position the medial point of nostril sill closure (and therefore the lateral point of nostril sill closure) more medially. This will shorten the third height, and as a result, less lateral lip element vertical height will be required to match this length. Conversely, in an incomplete cleft that presents a relative excess of vertical height, the third height can be lengthened by lateralizing the medial and lateral points of closure within the nostril (Fig. 19-15, *B*). More lateral lip vertical height can then be taken up by the longer third length. If vertical height excess persists despite this maneuver, it may be necessary to perform a medially based wedge excision of the upper lip below the lateral point of closure in the nostril sill (Fig. 19-15, *C*). The lateral apex of this wedge excision should never extend laterally beyond the subalare; this is unnecessary and leaves an unsightly scar. Care should be taken not to alter the vertical height of the lateral point of closure in the nostril sill, because it will compromise the final vertical position of the alar insertion.

A vermilion deficiency below the cleft-side half of Cupid's bow requires augmentation. An opening incision is created along the vermilion-mucosal junction below the cleft-side half of Cupid's bow. This backcut will receive a laterally based vermilion triangular flap from the lateral lip element, as described by Noordhoff.

In incomplete clefts, a wedge excision of the nostril sill above the medial and lateral points of nostril sill closure is performed. The excision should be sufficient to balance the circumference of the nares, with great care to prevent overresection, because the resultant nostril stenosis presents a difficult reconstructive challenge. The mucosa of the cleft margins is removed by wedge excision; a short, lateral, upper buccal sulcus advancement incision may be helpful.

In complete clefts, the mucosal incisions on the medial and lateral lip elements extend cranially to the points of attachment of each lip element to the greater and lesser alveolar segments, respectively. An upper buccal sulcus incision extending laterally from the point of attachment of the lateral lip element is made. A mucosal backcut can be incorporated as necessary. From the medial point of closure in the nostril sill, the incision continues intranasally along the caudal margin of the septum for a distance of up to 12 mm to facilitate access for septal repositioning. The lateral free edge of the septal flap will receive the medial free edge of the lateral vestibular

Fig. 19-15 Lateral lip markings will vary depending on the vertical height of the lateral lip element. **A**, In many complete clefts, the vertical height of the lateral lip element will be short. In such cases it is useful to position the medial and lateral points of nostril sill closure more medially, thus shortening the third height. The greater lip height incision on the lateral lip element will be more horizontal, and its lateral extreme may need to be coincident with the upper incision of the inferior triangle, which will require an upward-pointing orientation. **B**, With many incomplete clefts, the vertical height of the lateral lip element may be excessive. In this case, it is helpful to position the medial point of closure in the nostril sill more laterally. This essentially lengthens the third height. **C**, If the lateral lip remains too long despite this maneuver, a medially based wedge excision of the upper lip can be performed below the lateral point of closure in the nostril sill. The position of the point of closure in the nostril sill and of Noordhoff's point should not be compromised.

flap. The lateral vestibular flap is fashioned by incising from the lateral point of closure in the nostril sill to the attachment point of the lateral lip element to the alveolus and then along the piriform margin. This allows supraperiosteal mobilization of the alar base. An anteriorly based inferior turbinate flap may be incorporated to cover the vestibular lining defect in clefts with a significant AP distance between the greater and lesser maxillary segments.

Patients with a contralateral minor-form cleft should be considered for a synchronous bilateral cleft lip repair. This approach provides the best opportunity to achieve symmetry of Cupid's bow and of the resultant scar, and provides the ideal opportunity for reconstruction of the probial deficiencies of the cutaneous roll, vermilion, and median tubercle.

Primary Nasal Correction

The anatomic subunit approximation technique describes a technique for cleft lip repair. It can be accompanied by most previously described techniques of primary rhinoplasty.

Box 19-1 Goals for Primary Rhinoplasty

- Balanced alar bases (from the anterior view)
- Columellar base mobilization to the midline
- Caudal septal release and repositioning
- Alar base release and repositioning
- Release of the nasal attachments to the piriform margin
- Anteromedial advancement of the cleft-side dome and lateral crus
- Creation of the scroll—an internal nasal valve plication suture or sutures
- Lateralization of the cleft-side lateral vestibular lining—an alar transfixion suture or sutures
- No external skin incisions
- No excisions of the skin envelope

Because cleft nasal deformity is the result of an underlying skeletal deformity,^{35,36} the skeletal deformity needs to be corrected before a correction can be successful in the nose. Because pre-surgical orthodontics can only partially improve the deformity (by correcting maxillary segment malalignment while not addressing maxillary hypoplasia), and because primary bone grafting is not performed, completely correcting the nasal deformity at the primary operation is unrealistic. Patience is essential. The potential risks of a primary rhinoplasty include iatrogenic deformity of the skin envelope and cartilages and the introduction of scar that may complicate subsequent interventions. Skeletal base deficiencies can be augmented later at the alveolar bone grafting and orthognathic surgery if indicated. This will prepare the patient for definitive septorhinoplasty. Deformities such as a broad, deviated nasal dorsum, which are only obvious after maturity, may be addressed in this surgery. Definitive secondary septorhinoplasty will be successful only if the cartilages are intact and robust, and the skin envelope is complete and free of scar.

Our preferred primary rhinoplasty is relatively aggressive at the nasal base and relatively conservative in the lobule (Box 19-1).

A nasal stent is placed and secured with a transseptal suture. It is removed with the sutures after 1 week. The currently available stents do little to effect nasal tip position but are perceived to be helpful to smooth the nostril sill closure.

Management of the Cleft Alveolus

Our preferred method for managing the alveolar cleft involves presurgical nasoalveolar molding (for complete clefts), lip repair at 3 to 5 months of age (without gingivoperiosteoplasty), and secondary alveolar bone grafting before eruption of the adult cleft-side canine.

Surgical Technique

Local anesthesia is limited to bilateral infraorbital nerve blocks and for submucoperiosteal hydrodissection of the caudal septum. To prevent errors in measurement and in the perception of the balance of the repair, the lip elements are not infiltrated.

The repair should be performed in the proper sequence to allow the operator to assess progress (using the three checkpoints described in the following sections) and make modifications if necessary. The medial lip incisions (without the backcut) are made first.

First Checkpoint

The *first checkpoint* is the assessment of the length achieved by the Rose-Thompson effect alone. The 1 mm of calculated lengthening is an estimate. It will be greater when the slope of the bow is steeper: the more rotated the bow, the more acute the angle formed by the incision across the roll, and the greater the height incision, thus the greater the lengthening achieved as this angle opens to 180 degrees. Conversely, the more level the bow, the more obtuse the angle, and less the lengthening achieved by the Rose-Thompson effect. If the bow has been leveled by the Rose-Thompson effect, an opening incision and an inferior triangle will not be necessary. If an opening incision is deemed appropriate, it should be of sufficient length to level the bow.

Second Checkpoint

The *second checkpoint* is ensuring that the triangle that has been drawn on the lateral lip element is of the exact size to fill the defect created by the opening incision in the medial lip element once the bow has been leveled. The size of the triangle can be adjusted at this point if the lateral lip incisions have not already been performed.

Third Checkpoint

Once the medial and lateral lip elements have been fully mobilized from their skeletal attachments, the *third checkpoint* is performed—the approximation of the medial point of closure in the nostril sill with the lateral point of closure in the nostril sill. Before committing to the lateral point of closure, surgeons should check that the nares are of equal circumference, and that the cleft-side alar base has been sufficiently rotated to achieve symmetry with the noncleft-side alar base.

On the medial lip element, dissection between skin and muscle is limited to 1 mm from the incised margin to preserve the philtral dimple. Dissection between the skin and muscle on the lateral lip element is more extensive; skin is freed from the underlying muscle sufficient to advance the muscle relative to the skin and to release the bulge of the lateral lip. Muscle is approximated in a simple end-to-end fashion.

Absorbable monofilament sutures are used for the mucosa and muscular approximations. Skin is approximated with nonabsorbable sutures. Vermilion is approximated with braided absorbable sutures.

Postoperative Care

Elbow splints are worn for 2 weeks postoperatively. Patients may resume oral feeding immediately in the recovery room after surgery and are discharged on the following day if they are clinically well and oral intake is sufficient. Sutures are removed on the seventh postoperative day with the patient under general anaesthesia. The incision line is moistened with antibiotic ointment. Parents are instructed to keep the suture line clean and moist with Vaseline. A return visit is scheduled for 3 to 4 weeks postoperatively. Parents are given instructions regarding scar massage at this visit.

CASE EXAMPLES

This patient had a minor-form unilateral cleft and underwent an anatomic subunit approximation technique. In some cases, an inferior triangle is unnecessary, and the required lengthening can be obtained by the Rose-Thompson effect alone (Fig. 19-16).

This patient had an incomplete unilateral cleft and underwent an anatomic subunit approximation technique (Fig. 19-17).

This patient had a complete unilateral cleft lip and palate and underwent an anatomic subunit approximation technique (Fig. 19-18).

Fig. 19-16 A, The patient is shown preoperatively at 2 years of age. B, Immediate postoperative appearance. C, The patient is shown postoperatively at 5 years of age.

Fig. 19-17 A, The patient is shown preoperatively at 5 months of age. B, One-week postoperative appearance. C, The patient is shown postoperatively at 3 years of age.

Fig. 19-18 A, The patient is shown preoperatively at 6 months of age. B, One-week postoperative appearance. C, The patient is shown postoperatively at 5 years of age.

CONCLUSION

A unilateral cleft lip repair can provide reliable outcomes that minimize the stigmata of this congenital deformity. Many factors contribute to this achievement, most notably team care, which results in consistency in approach and careful follow-up. A balanced lip repair involves balancing the height deficiencies of the medial lip element with like tissue from the lateral lip element, while adjusting for the varying presentations of vertical height of the lateral lip element. Preserving the natural landmarks in both the medial and lateral lip elements will produce the most natural-appearing lip. Primary rhinoplasty should be performed judiciously and carefully to allow a definitive secondary septorhinoplasty. Although the techniques described in this chapter provide invaluable insight to understanding unilateral cleft lip deformities and have stood the test of time, experienced cleft surgeons may use other techniques with excellent outcomes. As with all reconstructive problems, evaluation and refinement of results in cleft patients are key elements for success.

KEY POINTS

Hoffman Surgical Technique

- Cleft lip can be diagnosed prenatally by ultrasound imaging as early as week 20 of gestation.
- Although syndromal associations are more common with isolated cleft palate than with cleft lip, a genetic evaluation is recommended for all children with cleft lip and palate.
- Reconstruction of the orbicularis muscle is critical to symmetry of the final lip repair and essential for normal lip growth.
- All lip repairs involve some degree of borrowing width to gain lip length, often in more than a single area of the lip.
- All key landmarks of the lip must be marked before infiltration of the lip with local anesthetic to prevent distortion of these landmarks.
- Mucosa should not be carried into the cutaneous flaps, because this will impart a permanent pink color to the scar.
- In a Millard type of cleft lip repair, the incision must not be carried around the alar base, because this will efface the alar-cheek junction. This is an extremely difficult problem to correct secondarily.

Continued

KEY POINTS (continued)

- In a primary nasal repair, releasing the lateral crus of the alar cartilage on the cleft side all the way down to the alar rim is critical.
- Nasoalveolar molding preoperatively may prevent the need for more extensive nasal dissection and release.
- Many authors advocate scar massage to decrease scar hypertrophy after cleft lip repair. How vigorously and frequently the parents perform this therapy will determine its effectiveness.
- In uncomplicated, isolated cleft lip repairs, attention to landmarks and all details of the repair will reduce the extent of secondary revision in most cases.
- Secondary surgery on the lip and nose is best delayed until the underlying bony and dental structures are as symmetrical as possible.
- Some degree of residual nasal asymmetry may be expected; generally, septorhinoplasty should be delayed until the time of skeletal maturity.

Fisher Anatomic Subunit Approximation

- The noncleft-side bow peak is marked on the vermilion-cutaneous junction where the straight part of the half bow meets the upper convexity of the lateral lip element. The cleft-side bow peak is placed an equal distance from the midline.
- A natural undulation of the cutaneous roll can only be achieved if the upward convexity of the lateral lip element lateral to Noordhoff's point is preserved.
- The transverse length of the cleft-side lateral lip element need not and should not be compromised to achieve vertical height.
- Leveling of Cupid's bow is the result of a Rose-Thompson lengthening effect in all cases. In most cases a small triangle is also placed above the roll.
- The orientation of the lateral lip element incisions vary depending on the vertical height of the lateral lip element.
- Vermilion deficiency below the cleft-side half of Cupid's bow should be augmented with vermilion from the lateral lip element.
- Medial incisions should be performed first. Lateral lip markings can be adjusted if necessary.

Bilateral Cleft Lip Repair

Brad T. Morrow • Donald R. Mackay

he complete bilateral cleft lip (CL) poses multiple complex challenges to the reconstructive surgeon. The protruding premaxilla and the poor quality of the prolabial soft tissue make the goal of achieving a symmetrical tension-free repair a daunting task. James Barrett Brown famously concluded that “the surgical repair of double cleft lips is about twice as difficult as in single clefts and the results are about half as good.”¹ This bleak view was largely the result of iatrogenic misadventures that are now well recognized and less commonly performed.

A classic example of resecting the protruding premaxilla or setting it back by resecting part of the vomer causes serious growth inhibition of the midface and markedly distorts the lip and nose.²⁻⁴ The use of banked forked flaps, which were used to elongate the columella in a delayed fashion, is another outmoded technique.⁵⁻⁷ Most surgeons now accept that the central white roll, vermillion, and mucosa are best reconstructed with tissue from the lateral lip elements and not the prolabium and that it is important to approximate the muscle from the lateral lip across the midline.⁸⁻¹⁰

ANATOMY

Normal Lip Embryology and Anatomy

Normal facial morphology results from the interaction of the five embryonic facial processes composed of neural crest and mesoderm-derived cells with an epithelial covering. The fronto-nasal and paired maxillary and mandibular processes undergo an intricate progression to fuse at the correct anatomic location.

The frontonasal process gives rise to the medial and lateral nasal processes, which form around the nasal placode. During week 6 to 7 of gestation, the medial nasal processes fuse and the maxillary processes merge to form the intermaxillary segment or the primary palate (Fig. 20-1).

The prolabium and premaxilla are formed from the frontonasal process, whereas the lateral lip elements and maxillary arches are derived from the maxillary processes.¹¹

The surface anatomy of the lip is divided into anatomic subunits consisting of the lateral lip elements, philtral columns, Cupid's bow, and median tubercle. The paired philtral columns separate the lateral lip elements from the philtrum. There is significant variation in the position of the philtral column at the lip-nose junction. Brooke et al¹² noted that most of the philtral columns originate lateral to the base of the columella rather than originating at the base of the columella. The double curvature of the lip resembles the bow of Cupid, the Roman god of love. There is significant variation in the depth of Cupid's bow between individuals, but all have paired convex peaks flanking a concave nadir. The median tubercle is a central area of fullness directly below Cupid's bow.

Three epithelial types distinguish the lip surface: (1) skin, (2) vermilion, and (3) mucosa. Each has distinct borders: the vermilion-cutaneous and vermilion-mucosal junctions. Mucosa and vermilion are completely separate entities, which are frequently incorrectly referred to as "dry vermilion" and "wet vermilion." Skin has stratified squamous epithelium and submucosal labial salivary glands. Vermilion is thinly keratinized stratified squamous epithelium without adnexal structures. Vermilion contains a high level of *eleidin*, a clear intracellular protein, which gives it the characteristic red color from the superficial blood vessels in the papillary layers.¹³ Mucosa is moist because of the salivary glands and is not normally exposed when the lips are in repose. The cutaneous roll or white roll consists of undulating, non-hair-bearing skin that separates the flat skin epithelium of the upper lip from the vermilion.

The orbicularis oris muscle forms a sphincter surrounding the upper and lower lips. The superficial component aids in facial animation and creates the philtral columns from decussating fibers inserting into the dermis. The deep component constricts the mouth to form a tight seal and puckers the lips.

Bilateral Cleft Embryology and Anatomy

In a complete bilateral cleft lip and palate (CL/P), the frontonasal process fails to fuse with the maxillary processes, creating a prolabium and premaxilla that are isolated from the lateral lip and maxillary arch elements.

The cleft prolabium is distinctive because of deficient soft tissues. The cutaneous portion lacks philtral columns. The normal vertical midline concavity is now convex. The cutaneous roll is hypoplastic and indistinct. The vermilion height of the prolabium is significantly reduced and hypoplastic compared with the lateral lip elements. A labial sulcus is generally absent. The prolabium does not contain any orbicularis oris muscle fibers. The premaxilla, no longer constrained by the maxillary arch elements, rotates anteriorly and elevates to an increasingly horizontal position.

The composition of the lateral lip elements is similar to the corresponding element in the unilateral cleft lip. Noordhoff's point¹⁴ describes the anatomic point on the lateral lip element where the vermilion-cutaneous and vermilion-mucosal junctions begin to converge. The cutaneous roll is well defined. Vermilion height is sufficient lateral to this point, but these structures become obscure and deficient medially. The orbicularis oris muscle fibers create a bulge as they abnormally insert into the alar base.¹⁵

The bilateral cleft nose deformity has the unique advantage of symmetry when compared with the unilateral cleft. The foundation of the deformity is based on a bilaterally hypoplastic maxilla. As the premaxilla protrudes, the lateral arch elements collapse, excluding the premaxilla from the arch. The bony derangement displaces the nostril bases laterally and posteriorly. The nasal tip broadens transversely and shortens sagittally. The lateral crura of the lower lateral cartilage lengthen and the medial crura shorten. This distortion results in medial displacement of the genua, effectively shortening the columella.¹⁶ As the lower lateral cartilages splay, the angle between the medial and lateral crura increases, which widens the soft triangle. The lower lateral cartilage and accessory cartilage complex attachment to the lateral piriform margin of the hypoplastic maxilla leads to posterolateral displacement and inward buckling of the ala and vestibular webbing.¹⁷ The abnormal insertion of the orbicularis oris muscle onto the alar bases contributes to their separation.

EPIDEMIOLOGY AND RISK FACTORS

The World Health Organization (WHO)¹⁸ recently reported the results from a study of an international database on orofacial clefts that collected reports from 54 registries in 30 countries. The population-based study included 7.5 million births and identified 7704 cases of cleft lip with or without cleft palate (CL \pm P). The overall prevalence was 9.92 per 10,000 for CL \pm P, 3.28 per 10,000 for CL, and 6.64 per 10,000 for CL/P. This was consistent with the prevalence of CL \pm P in the United States (10.2 per 10,000), the United Kingdom (9.45 per 10,000), and Western Europe (11.88 per 10,000), as well as previously published regional studies.¹⁹⁻²¹ This was in contrast to the finding of 20.4 per 10,000 in Japan, although a previous regional study in Japan reported a prevalence of 13.4 per 10,000.²² In addition, 76.8% of CL \pm P cases were isolated, 15.9% had malformations in other systems, and 7.3% occurred as part of a recognized syndrome. Of the registries recording laterality, 10.3% of CLs were bilateral and 30.2% of CL/Ps were bilateral.¹⁸ Multiple studies have noted that the prevalence of CL \pm P is approximately 2:1 in males to females.^{23,24}

There is a higher risk of syndromic conditions or additional malformations in patients with bilateral clefts, and bilateral clefts occur more frequently in stillborn and aborted fetuses than in live births.²⁵

Nonsyndromic CL is thought to be multifactorial in origin, with a combination of genetic and environmental risk factors. Although the literature is replete with potential causes of clefts, there have been few clearly established links.

Maternal environmental exposure has been extensively investigated. Maternal tobacco use and excessive alcohol consumption in the first trimester have been associated with an increased risk of clefts in a dose-response relationship.²⁶⁻³⁶ Several studies have found a protective effect of periconceptional folic acid consumption and a reduced risk for CL \pm P. However, the link is not as clear as it is for neural tube defects.³⁷⁻⁴⁰ Prescription medications with antifolate properties, corticosteroids, and anticonvulsants, such as carbamazepine, valproic acid, phenytoin, phenobarbital, and trimethadione, have been associated with an increased risk for CL \pm P.⁴¹⁻⁴⁴ Prepregnancy diabetes mellitus, but not gestational diabetes, and obesity have recently been linked to increased odds ratios for CL \pm P. The embryopathy is likely related to glucose intolerance and increased insulin resistance, but the exact mechanism has not been elucidated.⁴⁵⁻⁴⁸

PREOPERATIVE MANAGEMENT

Prenatal Diagnosis

The birth of a child is a life-changing event for any family and becomes of profound significance in the case of a facial anomaly. Since Christ and Meininger⁴⁹ initially reported on the detection of CL/P by ultrasonography in 1981, the initial presentation of a child with a cleft has drastically changed. In a recent systematic review of the literature, the detection rate of CL \pm P ranged from 9% to 100% in a low-risk population without a false-positive diagnosis. However, several of these studies lacked adequate sample size power calculations and contained selection bias.⁵⁰ Furthermore, recent technological advancements in antenatal ultrasonography have improved the detection rate of CL \pm P from 43% before 2007 to 86% after 2007.⁵¹ A similar detection rate of 81% was found in a prospective, nonselected, low-risk population of 35,924 women undergoing routine second-trimester prenatal ultrasonography in The Netherlands.⁵⁰

The prenatal diagnosis of a child with a cleft diagnosed by ultrasonography allows the surgeon to provide education, counseling, and support to the family, which can lessen the psychological impact at birth. Multiple studies have documented the positive effects of a prenatal diagnosis and that most families with an unsuspected child with a cleft would have preferred a prenatal diagnosis.⁵²⁻⁵⁴

There has been debate in the literature regarding the ethical issue raised by a prenatal diagnosis of a cleft, because it may increase the possibility of a termination of the pregnancy.⁵⁵⁻⁵⁹ Although there are case reports in the literature of pregnancy termination for isolated CL \pm P, a recent study in The Netherlands did not find any difference in early detection and termination of a pregnancy.^{51,52}

Multidisciplinary Care

All children with clefts should be managed by a multidisciplinary team approach with input from specialists in surgery, pediatrics, genetics, otolaryngology, speech therapy, dentistry, orthodontics, audiology, social work, and a team coordinator. A pertinent history should include information on the pregnancy course, maternal exposure to teratogenic substances, delivery complications, prematurity, birth weight, and a family history of clefts. A special focus must be directed toward birth weight to ensure that the child is gaining weight. Feeding counseling, including the use

of modified feeding bottles such as the Haberman or Pigeon, should be provided. The physical examination should differentiate patients with nonsyndromic from syndromic cleft lip, with a specific look for defects, such as trisomy 13 and 18, Van der Woude syndrome, and 22q11 deletion syndrome.

INDICATIONS AND CONTRAINDICATIONS

Bilateral CL repair is indicated at any age if the child is healthy. A still widely accepted guideline is the “rule of tens,” in which the child is 10 weeks of age, weighs 10 pounds, and has a hemoglobin level of 10 g/dl. These criteria usually indicate that the child is healthy and that it is safe to proceed with surgery. A few practitioners advocate early repair, but very few repairs are carried out before 3 months of age. If presurgical orthodontics is used, the repair is delayed up to 6 months until the treatment is completed.

There are no contraindications to bilateral CL repair in a healthy infant. However, if there are any associated congenital anomalies or syndromes, the repair should be delayed until the other issues are addressed. Safety is of prime importance. There is no medical urgency to repair a bilateral CL.

PREOPERATIVE PLANNING

Presurgical Orthodontics

A skilled orthodontist is an integral part of a multidisciplinary cleft care team. However, debate continues regarding the appropriate age for orthodontic intervention. Proponents of presurgical orthodontia stress the importance of restraining the uncontrolled growth of the premaxilla while still allowing for the expansion of the lateral alveolar segments. The intent is to approximate a normal arch relationship to reduce the alveolar cleft widths and decrease tension on the CL repair.⁶⁰

Presurgical orthodontics can be implemented by active or passive mechanisms. The active Latham device requires application with the patient under anesthesia in the operating room. Two custom-fitted acrylic plates are fixated with pins to the palatal shelves and a transverse wire loop through the premaxilla. An intraoral ratcheted screw is turned daily to expand the lateral segments while an elastic chain retracts the premaxilla.⁶¹

The passive technique consists of alveolar molding with a custom fitted acrylic plate that is initiated within the first 2 to 3 weeks of life. The plate is positioned in place with elastics taped to the patient's cheeks and must be worn at all times except for cleaning. Every week the patient is evaluated, and the plate is modified to allow retraction of the premaxilla and alveolar displacement by shaving and adding acrylic. Over 2 to 3 months, the alveolar clefts are reduced to less than 5 mm, and nasal stents are added to the plate to provide an anterior force to reposition the lower lateral cartilages and lengthen the columella.⁶¹⁻⁶³

Bilateral Lip Adhesion

Bilateral lip adhesion is not routinely performed, but it has proponents who use it when presurgical orthodontics is not available or in patients with a severely protruding premaxilla. The goal of a lip adhesion is to temporarily close the clefts to create a constraining force against the protruding premaxilla. This is not an aesthetic procedure; thus it should not interfere with the

subsequent reconstruction. When planning a bilateral lip adhesion, the definitive lip repair should initially be marked, and all incisions must be made with these boundaries so that the important landmarks are not distorted and remain free of scar tissue. The most significant disadvantage of the bilateral lip adhesion is that there is no muscle reapproximation, which may lead to dehiscence of the adhesion.

Premaxillary Setback

Primary repositioning of the extremely protruding premaxilla has been described in the literature, but this should be abandoned, because there is significant risk for inducing midface growth restriction. If absolutely necessary, premaxillary setback should be performed secondarily in conjunction with an alveolar bone graft in mixed dentition or a segmental LeFort I osteotomy in skeletal maturity.

SURGICAL APPROACH

Principles

Too many infants born with bilateral cleft lip undergo old-fashioned, often multistaged, procedures, and later have to endure sundry revisions throughout childhood and adolescence. Despite the surgeon's efforts, the stigmata of the repaired bilateral cleft lip and nose remain painfully obvious—even at close distance. To the contrary . . . the appearance of a child with repaired bilateral cleft lip should be comparable to, and in many instances surpass, that of a repaired unilateral complete cleft lip.

—John B. Mulliken

Dr. Mulliken's statement⁶² is no longer viewed as overly optimistic. Several crucial principles have been elucidated as the surgical approach to the bilateral CL has evolved. By adhering to the following principles, iatrogenic deformities can be reduced and a better aesthetic result can be anticipated.

Simultaneous Repair to Maintain Symmetry

The primary advantage of the complete bilateral CL compared with the unilateral CL is symmetry. If the bilateral repair is staged, as was previously recommended to reduce tension, then the advantage is squandered, because it is more difficult subsequently to achieve symmetry. Furthermore, scar formation may not be identical at different ages. Asymmetries tend to become more pronounced as the child grows and will necessitate revisions.

Reconstruction of the Upper Gingivolabial Sulcus

The upper gingivolabial sulcus is deficient or nonexistent in the complete bilateral CL. If the sulcus is not reconstructed, the upper lip remains tethered to the alveolus and affects the aesthetic and functional result. The upper gingivolabial sulcus is reconstructed with the prolabial mucosa. The vermilion and mucosa are separated from the prolabial skin, draped over the premaxilla periosteum, and sutured to the periosteum near the nasal spine. This flap should be thinned to the thickness of a graft to decrease the bulk. Mucosal flaps from the lateral lip elements will be approximated in the midline to re-create the anterior wall of the sulcus.

Reconstruction of the Central Lip From the Lateral Lip Elements

The prolabial cutaneous roll lacks definition and should not be used to reconstruct Cupid's bow. The prolabial vermilion is hypoplastic and narrow and should not be used to reconstruct the central vermilion and dimple. With insufficient vermilion, mucosa becomes included in the repair. This mucosa is very obvious as a red, dry, and chapped patch where one normally sees vermilion.

The Cupid's bow should be reconstructed with cutaneous rolls and vermilion flaps from the lateral lip elements. These flaps will contain good quality tissue if the discrete anatomic point that marks the convergence of the vermilion-cutaneous and vermilion-mucosal junctions (Noordhoff's point¹⁴) is precisely chosen. Care must be taken when marking this point, because incisions made medially will create flaps with a hypoplastic cutaneous roll and vermilion with insufficient height to re-create a full median tubercle. Conversely, if the incisions are made too far laterally, then the transverse length of the lateral lip elements will be unnecessarily shortened, resulting in a tight upper lip. The cutaneous roll and vermilion flaps are sutured in the midline, and the caudal edge of the prolabial shield will set the depth of Cupid's bow.

Cutaneous Shield From the Prolabium

In keeping with the cleft tenet of "discard little to no tissue," several of the initial repairs preserved all of the prolabial skin, which resulted in a disproportionately wide central segment.⁶³ The prolabial skin that is included in the lip repair should be a relatively small, symmetrical shield.

Muscular Reapproximation

The aberrant insertions of the orbicularis oris muscles must be completely dissected free from the alar bases. Failure to do so will result in muscular bulges in the lateral lip elements. Midline reapproximation of the orbicularis, if at all possible, is important in reconstructing the natural sphincter, which is the most effective constraining force against a protruding premaxilla.

Primary Rhinoplasty

Initial efforts to address the bilateral cleft nasal deformity were centered on the thought that cleft rhinoplasty should be primarily deferred so as to not interfere with the growth of the nose. Another prevailing thought was that the columella was deficient and must be augmented with tissue, such as forked flaps recruited from the prolabium or nostril sills.⁶

Dissatisfaction with the stigmata that remained from these approaches grew until such pioneers as Broadbent and Woolf,⁸ McComb,⁶⁴ and Ortiz-Monasterio and Olmedo⁶⁵ challenged these concepts. The paradigm began to shift from secondary to primary nasal correction based on the principle that "the columella is in the nose,"⁶⁶ and the shortened columella was the result of malposition of the lower lateral cartilages. Furthermore, primary cleft rhinoplasty was shown not to impair facial growth.^{17,65,67}

A brief review of the approaches to primary rhinoplasty will help to elucidate the contentious issues. McComb⁶⁸ described a "flying bird" incision across the lower aspect of the nasal tip, which continued bilaterally as alar rim incisions. The author thought that the accurate reapproximation of the alar cartilages, reestablishment of the columella, and narrowing of the nasal tip with a V-Y closure justified the creation of an external nasal scar⁶⁸ (Fig. 20-2).

Mulliken⁶⁹ championed bilateral alar rim incisions to access the middle crura and genua of the lower lateral cartilages. The domes are then approximated with an interdomal mattress suture. The lateral crura are also suspended to the ipsilateral upper lateral cartilages. Skin is excised from the soft triangle and lateral columella to narrow the tip, define the columellar-lobular junction, elongate the nostrils, and narrow the columellar waist⁶⁹ (Fig. 20-3).

Fig. 20-2 McComb's original "flying bird" technique for primary cleft rhinoplasty.

Fig. 20-3 Mulliken's technique for primary bilateral cleft rhinoplasty.

Trott and Mohan⁷⁰ extended bilateral alar rim incisions continuously with the prolabial shield incisions. The prolabium, columella, and nasolabial crease are then elevated as a single unit to gain open access to the nasal tip. Caution should be used with this approach, because the blood supply to the distal tip of the prolabium is based on the dorsal nasal skin and is at risk for ischemia. Cutting's approach improved the vascularity of the prolabial-columellar flap by elevating it at the membranous septum.⁷¹

Despite the more aggressive approach to a primary rhinoplasty, most patients will still require a secondary rhinoplasty to obtain an optimal result. Many authors correctly point out the long-term negative effects of poorly placed incisions on the skin that produce excessive scars. Incisions used for alar rim excisions, lateral rhinotomies, nasal tip access and resections, and primary columellar lengthening can cause secondary CL nasal deformities that are more difficult to correct than the natural deformity itself.

These authors argue that a conservative primary rhinoplasty should be used to limit iatrogenic deformities. Another reason to delay the definitive rhinoplasty is because the lower lateral cartilages are partially deformed as a result of maxillary hypoplasia at the lateral piriform margins and that to re-create the nasal tip and columella, the lower lateral cartilages must be anatomically repositioned on a corrected skeletal base. This is achieved only after appropriate alveolar bone grafting, orthodontics, and where necessary, orthognathic surgery. Performing a cleft rhinoplasty before these procedures may artificially alter the final aesthetic landmarks.⁷²

SURGICAL MARKINGS

The surgical markings and subsequent description of the technique have slight modifications to the Fisher technique. The markings and techniques of Fisher,¹⁶ Mulliken,⁶⁹ and Chen and Noordhoff¹⁴ are illustrated to highlight the similarities and differences (Figs. 20-4 through 20-6).

The essential objective of obtaining symmetry in a bilateral cleft lip repair starts with accurate preoperative marking.

A fine-tipped pen, either a sharpened Q-tip or fountain pen, is used to make the initial marks, which are then tattooed with a 25-gauge needle and dye. Gentian violet or brilliant green dyes are better options than the more commonly used methylene blue, which tends to “run.”

Fig. 20-4 Fisher's markings and technique. **A**, Point 1 marks the midline of the columella. Point 2 marks the midpoint of the prolabium, just above the deficient vermilion-cutaneous junction. Points 3 and 3' at the columellar base and 4 and 4' at the caudal end mark the outline of the tie-shaped prolabial skin. Point 5 is just lateral to the lip-columellar crease. Point 6 indicates the position of Noordhoff's point. Point 7 is marked just lateral to and above the cutaneous roll. Point 8 is below Noordhoff's point on the vermilion-mucosal junction. Points 6, 7, and 8 form a straight line perpendicular to the vermilion-cutaneous junction. Point 9 is marked just above the cutaneous roll lateral to point 7. The distance between points 7 and 9 should equal the distance between points 2 and 4. Point 10 is placed medial to the alar insertion and meets point 5 at the height of the lip repair at the anterior nostril sill. Point 11 is positioned near the cleft margin at a distance from point 9 that is equal to the distance between points 3 and 4 and at a distance from point 10 that is equal to the distance between points 3 and 5. **B**, Scar outline of a completed Fisher repair.

Fig. 20-5 Mulliken's markings and technique. **A**, Mulliken's technique uses anthropometric terms for the key points. The similarity to Fisher's points is readily apparent. **B**, Completed bilateral complete Mulliken cleft lip repair and primary rhinoplasty. (*prn*, Pronasale; *c*, highest point of columella nasi; *sn*, subnasale; *al*, ala nasi; *cphs*, crista philtri superior; *cphi*, crista philtri inferior; *ls*, labiale superius; *sto*, stomion.)

Fig. 20-6 **A**, Surgical marking after Noordhoff. Point 1 is the central point of the Cupid's bow. The lateral points of the Cupid's bow, on the right side (*cphr-2*), and on the left side (*cphr-3*) keep the total width of the Cupid's bow a maximum distance of 4 to 5 mm. The vertical limbs extend to the base of the columella, with the base narrowed to 3 to 4 mm wide. Points *cphr-2'* and *cphi-3'* are the anatomic points for the base of the philtral column on the lateral lip. These points are 3 to 4 mm lateral to the converging junction of vermilion and mucosa (red line) and the cutaneous roll. This point is where the vermilion first becomes its widest and is known as Noordhoff's point. The prolabial mucosa (*pm*) is used for reconstruction of the nostril floor. The central part of the prolabial mucosa is used for lining the premaxilla. **B**, The skin incisions are closed with fine absorbable sutures. Alar transfixion sutures (ATS) are placed to accentuate the ala-facial groove, support the lower lateral cartilage, and minimize vestibular webbing.

The surgeon should take the patient's race and parent's appearance into consideration when marking the philtral flap, but in general it is marked as a tie-shaped shield. Some authors have recommended that the shield width not be wider than 4 mm because of the widening that occurs as the child grows.^{73,74} This is probably less important than ensuring that the shield is symmetrical. The midpoint of the lip columella junction (1) and the midpoint of the prolabium in the normal skin just above the defective cutaneous white roll (2) are marked first. The width of the apex of the cutaneous shield is set by marking points 1.5 to 2 mm lateral to the central point in the lip-columellar junction (3,3'). Marks are also placed superiorly around the base of the columella (5,5').

The width inferiorly is set by making marks approximately 2.5 mm superolaterally on either side of the central point (4,4'). These points must be made cephalad to the deficient cutaneous roll of the prolabium and will become the peaks of Cupid's bow. The position of these two points will also determine the shape of Cupid's bow. As previously mentioned, the prolabial cutaneous roll and vermillion are of deficient quality and should not be included in the repair.

The markings for the lateral lip element begin at Noordhoff's point. This is the anatomic landmark at the convergence of the vermillion-cutaneous junction and the vermillion-mucosal junction with a full cutaneous roll (6,6'). This point must be accurately marked as shifting laterally and will include a full cutaneous roll and vermillion of sufficient height but will horizontally shorten the lateral lip. Conversely, shifting the point medially will include an ill-defined cutaneous roll and vertically deficient vermillion. Additional points are marked above the cutaneous roll at Noordhoff's point (7,7') and at the vermillion-mucosal junction below Noordhoff's point (8,8'). These points form a straight line perpendicular to the lateral lip element.

The location of the remaining points will depend on the prolabial markings. Another point is placed above the cutaneous roll lateral to the mark at the edge such that the length will match the midline to the superolateral points of the prolabial skin (9,9'). This will reconstruct the cutaneous roll above Cupid's bow.

A point located near the cleft margin such that this line is the same length as the lateral edge of the prolabial skin shield sets the vertical height of the lateral lip element (10,10'). Approximating the tissue along the cutaneous-mucosal junction, which is clearly seen intranasally along the anterior septum and nostril base, will close the nostril sill and anterior nasal floor (Box 20-1; see also Fig. 20-4, A).

Box 20-1 Bilateral Cleft Lip Markings

1. Midline of the lip-columellar junction
2. Midline cephalad to the prolabial cutaneous roll
3. Base of the philtral flap approximately 1.5 mm lateral to point 1 in the lip-columellar crease
4. Proposed peak of Cupid's bow approximately 2.5 mm superolateral to point 2
5. Nostril sill
6. Noordhoff's point
7. Cutaneous roll above Noordhoff's point
8. Vermilion-mucosal junction below Noordhoff's point
9. Lateral to point 7 above the cutaneous roll keeping lines 7-9 equidistant to lines 2-4
10. Vertical height of the lateral lip element keeping lines 9-10 equidistant to lines 3-4
11. Proposed closure of nostril sill keeping lines 10-11 equidistant to lines 3-5

SURGICAL TECHNIQUE

Bilateral infraorbital nerve blocks are performed with a 50:50 mix of 0.25% bupivacaine and 1% lidocaine with 1:100,000 epinephrine. In addition, the lateral lip elements, upper buccal sulcus, prolabium, alar bases, and inferior turbinates are infiltrated with local anesthetic.

After adequate time is allowed for the analgesic and vasoconstrictive properties to take effect, dissection is started on the prolabium.

An acute angle blade, such as a No. 11 blade scalpel, is used to incise the tie-shaped prolabial skin shield. When available we favor the use of a 300 disposable ophthalmic microknife. The incision is extended laterally around the base of the columella and then posteriorly around the premaxilla-septal junction, along the line of the skin and mucosa of the anterior nostril, which marks the medial edge of the cleft. A superiorly based mucoperichondrial flap is raised from the anterior septum for later closure of the nasal floor.

The prolabial shield is then cephalically elevated in a subcutaneous plane to the base of the anterior nasal spine. The skin lateral to the shield is deepithelialized to add bulk for the reconstruction of the philtral columns. A prolabial mucosal flap is caudally elevated in a submucosal plane. The flap should be thinned to the thickness of a mucosal graft. The mucosal flap is inset over the anterior premaxilla with a 5-0 absorbable horizontal mattress suture to the premaxillary periosteum to reconstruct the posterior wall of the gingivobuccal sulcus (gingival surface of the prolabial alveolus) (Fig. 20-7).

The lateral lip elements are addressed first with a full-thickness, perpendicular incision to the lateral lip element starting at the cutaneous roll above Noordhoff's point (point 7) and then continuing perpendicularly through the vermilion and mucosa of the inferior aspect of the lip (lines 7 and 8).

An incision is now made from the lateral point above the cutaneous roll to the nostril base. The incision continues superiorly and posteriorly along the junction of the cleft margin and nasal vestibular mucosa at the base of the inferior turbinate. A superiorly based mucoperiosteal flap can be raised from the inferior turbinate to help with closure of the nasal floor. A strip of the cleft margin is excised down to the convergence of the CL, alveolus, and vestibule. The excised cleft tissue is discarded.

An upper buccal sulcus incision is made laterally from the cleft margin. The alar base is freed from the piriform rim in a supraperiosteal plane. This dissection needs to be extended laterally and superiorly enough to allow complete mobilization of the soft tissue of the lateral lip element and the alar base to close without tension. The extent of the dissection will often extend to the infraorbital nerve, and care should be taken not to injure the nerve.

The orbicularis oris muscle is freed from the abnormal attachment to the piriform rim as part of the dissection releasing the alar base. It is also freed from the alar base using scissors to dissect from the labial and nasal layer up to the subdermis of the alar groove. The remaining dissection separates the orbicularis from the skin, mucosa, and vermilion.

Closure starts by suturing the nasal floor with a 5-0 suture on a small semicircular needle, such as a G-2 needle. If needed, a superiorly based inferior turbinate flap is used to close the posterior part of the nasal floor, suturing the inferior turbinate flap to the septal mucoperichondrial flap. Suturing the junction of the skin-mucosal junction from the alar base laterally and the septum medially aligns the anterior part of the nasal floor closure.

Fig. 20-7 Creation of the labial sulcus. The prolabial mucosa is thinned and then sutured near the base of the columella to line the prolabial alveolus.

Mucosa from both lateral lip elements is advanced to the midline and approximated with 4-0 chromic sutures. The superior aspect of the lateral lip mucosa is anchored to the premaxilla periosteum to set the depth of the gingivobuccal sulcus.

The lateral lip vermilion-mucosal junctions are approximated with a 4-0 chromic suture. The muscle approximation starts with an interrupted suture in the pars marginalis of the muscle that has been dissected from the vermilion and mucosa. This suture is left long, and a downward tension on this suture facilitates the progressive approximation of the muscle with buried 4-0 absorbable sutures.

The vermilion, skin, and nostril sill are approximated with interrupted dermal 5-0 absorbable sutures. Final closure is then achieved with interrupted 6-0 rapidly absorbing sutures or even cyanoacrylate glue if the edges are well approximated.

We currently perform a McComb type of primary cleft rhinoplasty.⁶⁷ The lower lateral cartilages are freed from the overlying nasal skin by dissecting from the open wound at the nostril bases and the base of the columella. The dissection is carried over the domes of the lower lateral cartilages, and the tissue is freed from between the two medial crura. The dissection is carried up onto the nasal dorsum and above the upper lateral cartilages. Alar transfixion sutures are then placed with the use of an absorbable monofilament such as 4-0 PDS to approximate and elevate the domes of the lower lateral cartilages. These sutures are tied intranasally and have the effect of refining the nasal tip and lengthening the columella. Additional bolster sutures help shape and contour the nostril sidewalls and bases as illustrated in Fig. 20-6, *B*.

POSTOPERATIVE CARE

Patients are allowed to resume oral intake with the same bottle they used preoperatively or the breast in cases of isolated cleft lips. Intravenous fluids are continued until adequate oral intake is achieved. Patients are discharged the same day as surgery with postoperative instructions regarding incision care and a limited course of liquid narcotic pain medication. The vast majority of patients have transitioned to only acetaminophen for pain control by postoperative day 1. All cutaneous sutures are absorbable and do not require removal.

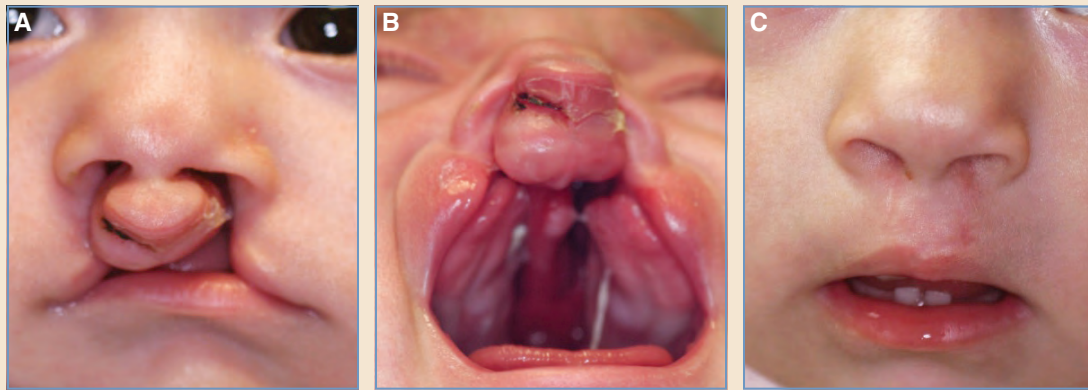

Fig. 20-8 A and B, Preoperative bilateral CL/P with prominent prolabial segment. C, One year after surgery.

Arm restraints are not used in our patients. In addition to being irritating to the patient, splints do not decrease complications such as dehiscence or fistulas when compared with non-restrained patients. The children very quickly grasp that interfering with the new repair hurts and instinctively protect themselves.⁷⁵ Follow-up is arranged within 2 weeks, at which time the parents are instructed on scar massage. A clinical example is shown in Fig. 20-8.

COMPLICATIONS

Although infants are obligate nasal breathers, this is generally not an issue at 3 months of age, and airway obstructions are exceedingly rare. Anesthetic complications are also rare and can be minimized by including a pediatric anesthesiologist in the multidisciplinary care. Bleeding, infection, and dehiscence are infrequent and can be managed with meticulous hemostasis and local wound care. Late scar revisions are the most frequently required, but true hypertrophic scars are uncommon.

Incomplete Bilateral Cleft Lips

Bilateral CL can present as a broad spectrum encompassing symmetrical complete, symmetrical incomplete, and asymmetrical variants. An asymmetrical bilateral CL may be complete or incomplete, with a contralateral incomplete or lesser form cleft (minor, microform, or mini-microform).⁷⁶

Symmetrical incomplete bilateral clefts may require additional tissue resection because of the long lateral lip elements. These resections should be placed medial to the alar base. The muscle closure is approached in the same way as a complete cleft, and the vermilion reconstruction should rely on the lateral lip elements. The buccal sulcus and nasal floor do not need to be addressed.

Asymmetrical clefts are challenging and must be repaired asymmetrically, with additional tissue resected medial to the alar base on the incomplete side. Asymmetrical clefts with a lesser form pose a challenge regarding the extent of the repair and will depend on whether the lesser

form even requires a correction. If the deformity is minimal, then the contralateral side can be repaired as a unilateral cleft. If the deformity is significant, then the repair should proceed as an asymmetrical bilateral CL.

Secondary Cleft Rhinoplasty

Despite the trend to perform more aggressive primary cleft rhinoplasties, secondary cleft rhinoplasties are still frequently necessary. Ideally, the secondary cleft rhinoplasty is performed after skeletal maturity and any orthognathic surgery. However, if the deformity is severe or the child is suffering from any psychological stress, such as teasing, an earlier correction should be undertaken.

Secondary rhinoplasties to correct bilateral clefts usually have to deal with a short columella, a wide poorly defined nasal tip, and splayed nostril bases. Correction requires a combination of an open approach, extensive mobilization and repositioning of the lower lateral cartilages, nasal osteotomies, and extensive use of cartilage grafts.

CONCLUSION

A bilateral CL/P represents the extreme form of clefting and a real challenge to the family and team taking care of the child. Improvements in high-resolution ultrasound technology have increased the frequency of prenatal detection and diagnosis, which in turn has allowed us to do a better job of preparing parents for the birth and subsequent treatment. Advances in nasosulveolar molding have also improved the initial outcomes and certainly improved the outcomes when addressing the vexing problem of a short columella.

KEY POINTS

- All children with clefts should be managed by a multidisciplinary team, with initial counseling on feeding techniques.
- Premaxillary setback will cause serious midface growth restriction.
- A bilateral CL should be repaired simultaneously to preserve symmetry.
- The cleft prolabium contains several deficiencies. The cutaneous roll and vermilion height are hypoplastic, and there is an absence of orbicularis oris fibers or philtral columns.
- Cupid's bow should be reconstructed with cutaneous rolls and vermilion flaps from the lateral lip elements.
- Preservation of all of the prolabial skin will result in a disproportionately wide central segment. The prolabial skin should be used to create a small, symmetrical, cutaneous shield, with which to form the philtral columns.

Continued

KEY POINTS (continued)

- The upper gingivolabial sulcus is deficient or nonexistent. A caudally based prolabial mucosal flap is draped over the premaxilla to reconstruct the posterior border of the sulcus. Mucosa from the lateral lip element will reconstruct the anterior border of the sulcus.
- The orbicularis oris muscle must be completely freed from the abnormal insertions on the alar bases and lateral lip skin. Reapproximation in the midline provides a constraining force against the protruding premaxilla.
- The nostril floor can be closed with a superiorly based mucoperiosteal flap based on the inferior turbinate and septum.
- The shortened columella is caused by malposition of the lower lateral cartilages. Banked forked flaps should be abandoned and not used to elongate the columella. Primary cleft rhinoplasty has not been shown to impair facial growth.

ACKNOWLEDGMENT

We acknowledge the authors of the first edition of this chapter, Andre Panossian and David M. Fisher. Much of this chapter is based on their work.

Secondary Deformities of the Cleft Lip and Nose

Jeremy P. Warner • Bruce S. Bauer

Most cleft lip patients seen for revision have relatively minor deformities, because the principles described in Chapters 19 and 21 were followed for the primary repair, with attention to the critical landmarks and meticulous technique. A cleft lip nasal deformity may be the most visible evidence of a prior cleft. Busy cleft surgeons see patients whose lip repairs were carried out by less skilled surgeons and whose complications of healing and scar management have resulted in quite significant deformity. Revisions range from minor realignment of landmarks with direct excision or Z-plasty to major revisions involving full-thickness layered repair or Abbé flap reconstruction. This chapter presents a review of the more common minor revision procedures and a discussion of the principles of major lip revision. The main focus is an in-depth discussion of the treatment of secondary deformities of the cleft lip nose.

We think that a thorough understanding of the nasal deformities seen and the procedures required to correct them best begins with a brief discussion of the primary deformities of unilateral and bilateral clefts. Surgeons' opinions vary regarding the appropriate degree of primary correction and how much of the deformity remains for secondary correction. Most surgeons who routinely perform cleft lip repair agree that an uncorrected nasal deformity will belie even the best lip repair and invisible scar. Excessive dissection in a primary nasal repair may affect long-term nasal growth. Surgeons respect this to various degrees depending on their comfort level. Therefore the spectrum of secondary nasal deformities varies from minor asymmetries to marked asymmetry, hypoplastic growth, and airway obstruction at skeletal maturity.

SECONDARY LIP DEFORMITIES

Isolated secondary lip deformities can develop in an otherwise well-performed lip repair and can be corrected by minor revisions. When a primary repair was not performed optimally, these deformities may not be isolated and are better addressed by a major revision. Lip shape, symmetry, movement, and associated nasal symmetry are dependent not only on alignment of the soft tissue landmarks, but also on the bony support beneath the lip and nose. Proper release of the soft tissues during a repair may provide excellent symmetry even in the presence of underlying maxillary hypoplasia, but failure to fully release the lip and nasal structures can result in significant collapse of the soft tissue with increased deformity even when the lip has been well repaired otherwise. Most lip revision procedures are relatively straightforward, whereas others defy simple explanation. For these cases, surgeons need to “separate the parts” and occasionally rely on basic plastic surgical ingenuity to place them in the final symmetrical position (Fig. 21-1).

Fig. 21-1 **A**, Relatively minor asymmetry with fullness of the vermilion and mucosa, symmetrical lip length and shape of the Cupid's bow, and drift of the alar base. **B**, Symmetry of the lip and nose is overshadowed by the significant collapse of the alar base and heminose, which resulted from a pronounced deficiency of the underlying bone. **C**, Although the nose is relatively symmetrical, the repair did little to align the lip landmarks or correct the underlying muscle. What remains is similar to an occult cleft. **D**, Initially, this appeared to be a slightly short cleft side with a displaced columella. It was actually related to the whole lip being oriented off midline, with the columella vertically in line with the high point of the Cupid's bow. **E**, In this case, the deformity of the lip and nose are from an atypical shift of the columella to overlie the normal peak of the Cupid's bow. This may have happened secondary to early overresection in the nostril floor on the noncleft side. The lip is elongated on the normal side to a greater degree than it is short on the cleft side. **F**, This bilateral repair is similar to a lip adhesion, because it lacks a muscle repair and alignment of the vermilion-cutaneous or vermilion-mucosal junction to augment the central tubercle.

Minor Revisions of the Lip and Nose

Alar Base

Alar base asymmetry is a universal feature of primary cleft deformity and is not always in proportion to the degree of lip clefting.¹ Because skeletal deficiency is generally not corrected at a primary repair, some degree of residual alar base asymmetry in the AP dimension is frequently present in the secondary deformity. The repositioned alar base tends to drift posteriorly after repair, reflecting the severity of the original and uncorrected skeletal base asymmetry (cleft-side maxillary hypoplasia)² (see Fig. 21-1, *A* and *B*). Both the soft tissues and the underlying skeleton need to be considered before attempting to correct this problem; therefore the timing should be decided based on the degree of underlying skeletal support. The debate regarding the pros and cons of primary bone grafting is discussed in Chapter 28. However, early placement of a primary graft may have the advantage of improving the skeletal support.^{3,4} The choice of procedure for correcting the drift of the alar base depends on the direction of distortion.

In cases in which the alar base position is significantly affected by the underlying bony hypoplasia (see Fig. 21-1, *B*), it is best to wait until after an alveolar bone graft and graft to the piriform margin. If the vertical height of the lip is in balance, with the peak of the Cupid's bow on the normal and cleft side symmetrical, minor asymmetries of the alar bases in the vertical dimension can be addressed by a Z-plasty. If the alar insertion is too low, reciprocal transposition of the alar base with a triangle taken from cephalad within the nostril sill and vestibule can be helpful; however, care must be taken not to introduce skin of different character (thickness, color, hair, and scar) onto the upper lip (Fig. 21-2, *A*). If the alar insertion is too high, reciprocal transposition of the alar base with a triangle taken from the upper lip can be performed (Fig. 21-2, *B*). In general, if the transverse wedge resection is confined to the skin and subcutaneous tissue, the likelihood of elevating the lip on that side is minimal (Fig. 21-2, *C*). (A full-thickness excision,

Fig. 21-2 Alar base repositioning. **A**, Z-plasty to elevate an alar insertion. **B**, Z-plasty to lower an alar insertion. **C**, An elliptical excision.

Fig. 21-3 Vertical lengthening. **A**, A Rose-Thompson excision. **B**, Z-plasty.

including muscle, with fixation sutures along the piriform margin may not fully correct a vertically long lip.) For patients who have already had a graft and have good skeletal balance without the need for a maxillary advancement, a triangular-shaped, composite graft of conchal cartilage with attached postauricular fascia and fat creates an excellent, stable additional platform to elevate the alar base. The graft can be set through an incision in the nostril sill or along the medial edge of the alar base.

Nostril Sill

The nostril sill may be inappropriate in width, depressed, or excessively scarred. A broad sill can be reduced fairly easily with an elliptical excision. Great care is needed during the primary procedure to preserve the nostril sill to prevent a constriction of the nares. A sill that is too narrow can be augmented with skin from the upper lip (see Fig. 21-2, *A*) or lateral to the alar crease (see Fig. 21-2, *B*), but not without introducing a donor-site scar. A depressed nostril sill is rarely seen in isolation. It can result from an incomplete muscle repair and present with a lateral lip muscular bulge. Treatment is therefore done in concert with excision of the cutaneous lip scar, including scar through the area of muscle dehiscence, and muscle lengthening with interdigitating muscle bundles (Figs. 21-3, *A*, and 21-4, *A* and *B*). As part of a major lip revision, this maneuver is more likely to lengthen a shortened lip (and effect a lowering of the peak of the Cupid's bow) than a small Z-plasty (as shown in Figs. 21-3, *B*, and 21-4, *A* and *B*). Therefore it is generally best treated by a major revision.

Cutaneous Lip

As with scar revision, revising the cutaneous component of a lip repair scar should be considered if it can improve the scar appearance. However, a major revision offers an opportunity to repo-

sition a scar to better mirror the philtral column on the noncleft side. For this reason, it may be preferred over a minor revision. Although past dogma suggested that the best lip scar resulted from early repair, meticulous closure and active massage in the months after surgery probably produces a better scar. Even a new scar will be less visible if overall lip symmetry is improved.

Minor vertical height deficiencies (up to 1 mm) from underrotation of the cleft-side peak of the Cupid's bow can be corrected using a Rose-Thompson excision and closure^{5,6} (see Fig. 21-4, A). Moderate vertical height deficiencies greater than 1 mm can be corrected with a Z-plasty. The lower portion of the lip scar is opened or elliptically excised, with or without excision of the upper lip scar as indicated, and a small opening incision is made above the white roll in the medial lip element to adequately lower the cleft-side peak of the Cupid's bow. The resultant defect is then filled with a triangular flap equal in size to the defect pared from the lateral lip element (see Fig. 21-4, B). If a Rose-Thompson lengthening is incorporated into the design, the triangular flap need not be large (see Fig. 21-4, C).

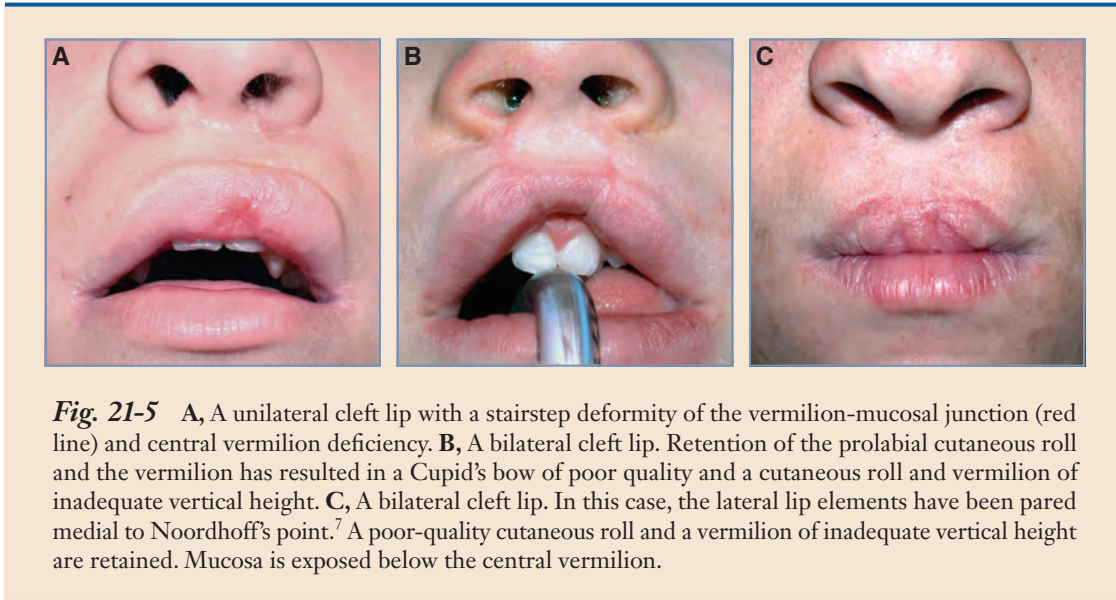

Fig. 21-5 A, A unilateral cleft lip with a stairstep deformity of the vermilion-mucosal junction (red line) and central vermilion deficiency. B, A bilateral cleft lip. Retention of the prolabial cutaneous roll and the vermilion has resulted in a Cupid's bow of poor quality and a cutaneous roll and vermilion of inadequate vertical height. C, A bilateral cleft lip. In this case, the lateral lip elements have been pared medial to Noordhoff's point.⁷ A poor-quality cutaneous roll and a vermilion of inadequate vertical height are retained. Mucosa is exposed below the central vermilion.

Significant vertical height discrepancies often occur in combination with other deformities and are usually best managed by a major revision.

Vermilion-Cutaneous Junction

The initial repair is the best time to correctly align the vermilion-cutaneous and vermilion-mucosal junctions. As emphasized in Chapters 19 and 20, correctly choosing Noordhoff's point and correcting a medial vermilion deficiency are critical. Discrepancies are corrected using standard maneuvers to match adjacent flap lengths.

Small stairstep deformities (1 mm or less) of the vermilion-cutaneous junction can be corrected with a vertical incision through the scar and translation of the medial and lateral lip elements (Fig. 21-5, A). Larger stairstep deformities (greater than 1 mm) may be corrected with a Z-plasty, transposing a vermilion triangle and cutaneous roll triangle from either side of the vertical scar (Fig. 21-5, B and C). If a stairstep deformity accompanies an underrotation of the medial lip, a major revision is preferred.

Vermilion

In all but the very minor forms of unilateral cleft lip, the vermilion below the cleft side of the bow is deficient in height. If this is not augmented with vermilion from the lateral lip element during the primary repair, a stairstep deformity of the red line (vermilion-mucosal junction) will be present, including central vermilion deficiency and exposure of mucosa (Fig. 21-6, A). The exposed mucosa is different in color from adjacent vermilion. Because it is not keratinized, it dries easily with resultant cracking, chapping, and peeling. Patients habitually lick the area or use lip balm. Although augmenting the vermilion as an isolated secondary procedure is difficult, it is usually possible as part of a major lip revision (see later section on Major Lip Revision). Augmenting deficient vermilion during a primary operation is easy; therefore primary prevention is preferable to secondary treatment. In a bilateral cleft lip, the vermilion of the prolabium is extremely short in height. If the central red lip is reconstructed using the red lip of the prolabium, as with a Manchester repair,⁸ or if the white roll flaps of the lateral lip elements were pared too medially

Fig. 21-6 A, A unilateral cleft lip and palate. B, The vermilion-cutaneous junction (*red dashed line*) and the cutaneous roll (*white dashed line*) of the lateral lip element are relatively parallel lateral to Noordhoff's point (*yellow arrowhead*). The two lines converge medial to Noordhoff's point. Cupid's bow on the noncleft side (*red arrowhead*), and the low point (*white arrowhead*) and planned position for the high point of Cupid's bow on the cleft side, are also shown.

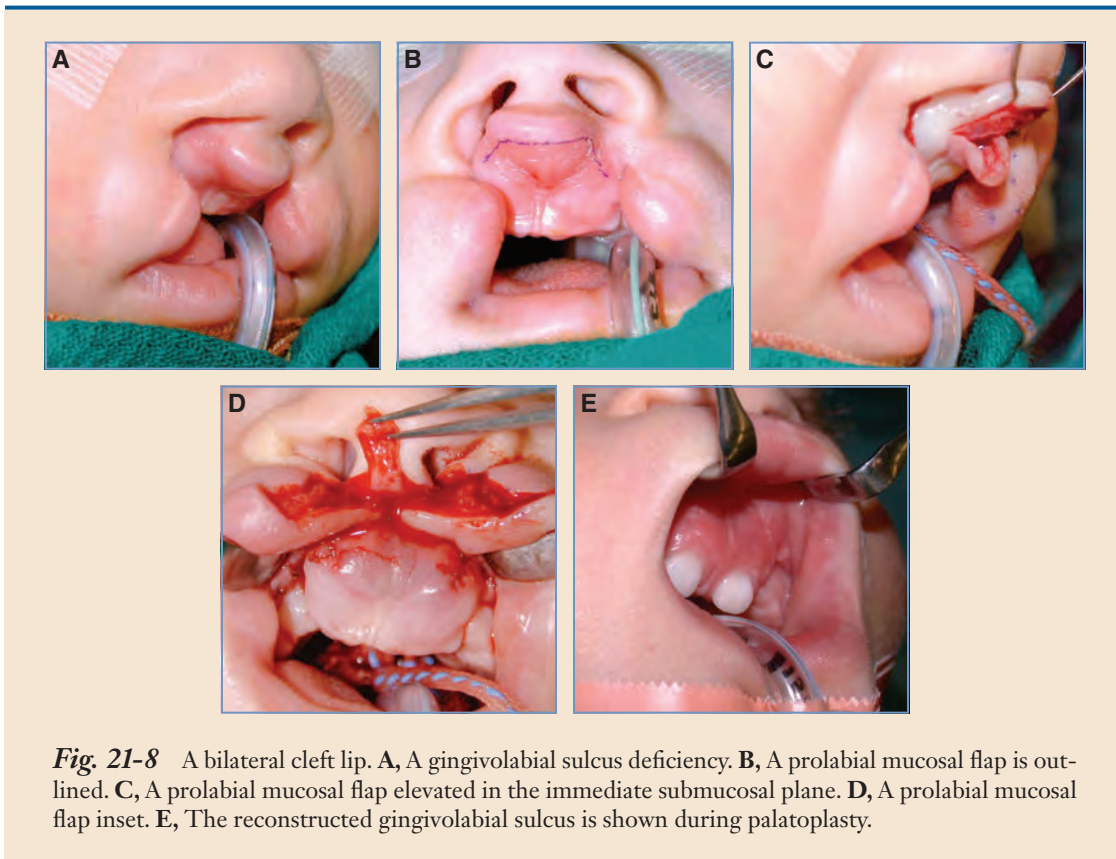

Fig. 21-7 Red lip revision by a transverse elliptical excision of mucosa preserves vermilion.

and carried with them vermilion of insufficient vertical height (see Fig. 21-5, C), central vermilion will be deficient and mucosa exposed. This situation generally requires a major lip revision.

The vermilion tends to heal nicely; however, the underlying scar can be excessive and add bulk to the free border of the lip. Some resolution of this swelling may occur long after the scar of the cutaneous lip has matured. If the swelling persists after 2 to 3 years, revision of the red lip should be considered. The red lip can be revised by either a transverse or vertical elliptical excision. A transverse reduction is often preferable (Fig. 21-7). Reduction of the excess by a transverse elliptical excision of mucosa behind the red line preserves vermilion and prevents a dog-ear deformity and extension of the scar onto the cutaneous lip.

Mucosa and Gingivolabial Sulcus

Primary surgery presents an ideal opportunity to create a generous and functional central upper gingivolabial sulcus⁹ (Fig. 21-8). A secondary deficiency of the central gingivolabial sulcus has both aesthetic and functional consequences; accordingly, numerous procedures for secondary correction of a gingivolabial sulcus deficiency have been described. Mucosal grafts may be required if no sulcus is present.¹⁰ For lesser deficiencies, an inverted-U-shaped flap of Erol and Ağaoğlu is effective.¹¹

Lateral Lip Deficiency

In the primary state, the transverse dimension of the cleft-side lateral lip (from the commissure to the peak of the Cupid's bow) is almost universally shorter than that of the noncleft side.¹² When the lateral lip is also deficient in height (from the subalare to the peak of the Cupid's bow), primary repair is more difficult. Because there is no way to increase the transverse length of the lateral lip, preservation of this length is required at the primary repair. Depending on the type of repair used, it may be necessary to further compromise the transverse length of the cleft-side lateral lip element to achieve the required vertical height. Inferior triangle repairs require less compromise of the transverse length than do rotation-advancement repairs, and they should be considered for repairing lips that have combined vertical and transverse deficiency of the cleft-side lateral lip.⁵

Volume

Augmentation cheiloplasty should be considered if the volume of an otherwise well-balanced lip is deficient. Whistle deformities generally are a combination of underrotation and central vermilion deficiency. These deformities are not corrected by volume augmentation. Many injectable filler preparations and implants are available, associated with various profiles of immune acceptance, retention, and duration of volume.² We prefer autologous free grafts to these preparations and favor the use of temporal fascia, as described by Chen et al.¹³ Temporoparietal fascia is preferable to dermal fat grafts, because it lacks dermal elements and the donor scar is inconspicuous.

Major Lip Revision

A major lip revision should be considered when the deformities described previously occur in combination. Takedown of the previous lip repair and complete revision of the repair with excision of all or most of the old scar can dramatically improve secondary deformities.^{14,15} When little tissue has been discarded and all the key landmarks are present, the previous repair can be treated much like a lip adhesion and excised within the lines of a definitive repair (Figs. 21-9 and 21-10). Occasionally, when this is not the case, an all-out effort should be made to preserve the existing key landmarks. If the key landmarks have already been discarded or distorted, an Abbé flap should be considered¹⁶ (Figs. 21-11 and 21-12).

The surgical goals of a major lip revision are similar to those of a primary repair²:

- Key landmarks are maintained.
- Tissue is thoughtfully discarded.
- Scars are placed along natural lines/seams of anatomic subunits.
- Muscles are aligned and repaired.
- The Cupid's bow is balanced.
- Symmetry is ensured.

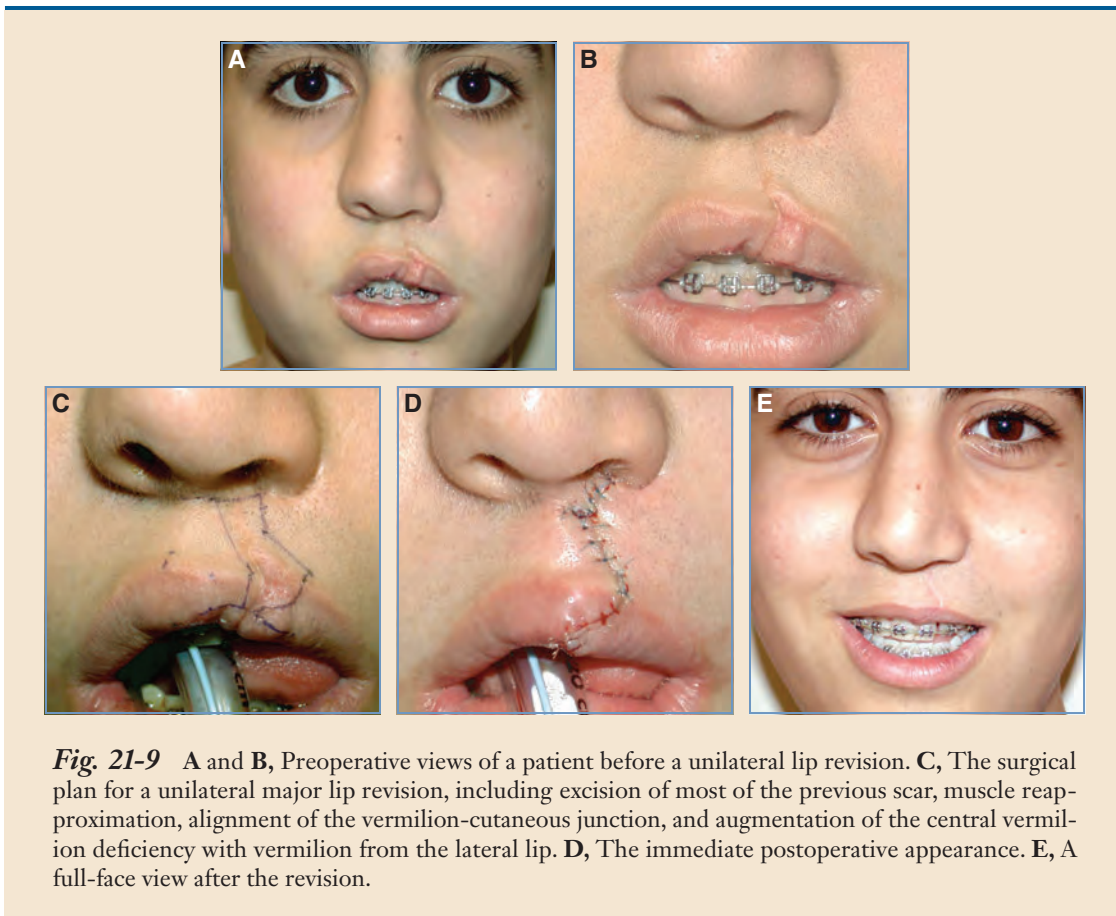

Fig. 21-9 A and B, Preoperative views of a patient before a unilateral lip revision. C, The surgical plan for a unilateral major lip revision, including excision of most of the previous scar, muscle reapproximation, alignment of the vermilion-cutaneous junction, and augmentation of the central vermilion deficiency with vermilion from the lateral lip. D, The immediate postoperative appearance. E, A full-face view after the revision.

Fig. 21-10 A, A bilateral major lip revision. Preoperatively, the lateral lip elements have been paired medial to Noordhoff's point. A poor-quality cutaneous roll and a vermillion of inadequate height are retained. Mucosa is exposed below the central vermillion. B, The surgical plan includes excision of much of the previous scar; reduction of the prolabial skin to a small cutaneous shield; excision of the poor-quality Cupid's bow, exposed mucosa, and medial vermillion; the use of cutaneous roll-vermillion flaps designed lateral to Noordhoff's point; and muscle reapproximation. C, The immediate postoperative appearance. D, A full-face view 1 year postoperatively.

Fig. 21-11 A, An Abbé flap or "lip switch" allows replacement of deficient central lip, while reducing the hypertrophied lower lip. It also provides additional tissue for the columella and releases tension on the nasal tip.

Fig. 21-11, cont'd B-D, Preoperatively, the lip is short, tethered, and out of balance with the hypertrophied lower lip. The nose is tethered from the short columella. The overall impression is of significant class III skeletal relationships. E, The change in lip balance 1 week after division of the Abbé flap pedicle. The patient underwent a bilateral otoplasty simultaneously, and conchal cartilage was placed in the nasal tip in a configuration mimicking that of the normal alar cartilages. F and G, AP and lateral views show improved lip balance and, through soft tissue changes alone, a suggestion of corrected maxillary deficiency.

Fig. 21-12 Two cases are presented in which lip asymmetry and marked nasal asymmetry arose from early repairs and resulted in varying degrees of columellar displacement over the peak of the Cupid's bow. A, Although this patient's lip was well shaped, with well-repaired underlying muscle, it was short on the cleft side, and the nose was deviated to the cleft side. B, The lip was released from alar base to alar base along the nostril sill. This freed the columella to move toward midline and shifted the tissues to the right. The lip descended, matching the normal lip length and allowing correction without taking down the cutaneous scar.

Continued

Fig. 21-12, cont'd **C**, This patient's columellar base was over the peak of the Cupid's bow on the noncleft side. The preoperative appearance suggested the nasal pyramid was markedly asymmetrical. The entire lip was taken down and revised using the basic principle of anatomic subunit repair. The lip shifted along the line from alar base to alar base, extra tissue from the nostril sill on the left moved across to the right, and the columella was allowed to move midline. **D**, The result of the revision suggests that a full rhinoplasty was performed. However, this atypical major revision of the lip with minor trimming of the cleft-side alar margin was all that was required after shifting the lip soft tissue and centralizing the columella.

SECONDARY CLEFT LIP NASAL DEFORMITIES

Secondary cleft nasal deformities vary significantly based on the extent to which each surgeon followed the lip repair principles described in Chapters 19 and 20 and addressed the nasal deformity during the initial cleft repair. Although some surgeons prefer to correct the nasal deformity when the underlying skeletal deficiency can be corrected, others think that adequate release of the nasal soft tissues, repositioning of the displaced cartilages, and filling of the deficient lining tissue helps to obtain excellent symmetry even in the presence of hypoplastic skeletal support.^{7,17-19} We have just seen how the correction of both minor and major secondary lip deformities can improve the residual nasal deformity. We will now focus on the anatomy of both unilateral and bilateral cleft lip nasal deformities, the steps by which the greater part of the deformity can be corrected early, the extent to which intermediate repair can further improve the deformity, and the maneuvers necessary to complete the reconstruction after skeletal maturity.

Primary Cleft Nasal Deformities

Unilateral Cleft Nasal Deformity

The anatomy of a *unilateral cleft nasal deformity* is the result of hypoplasia or distortion of the underlying bony and cartilaginous components and alteration of the soft tissue envelope, which affects the deformity to varying degrees^{7,17-21} (Figs. 21-13, *A* through *C*, and 21-14, *A*). The deformities include the following:

- The caudal septum deviates toward the noncleft side and is convex to the cleft-side airway.
- The cleft-side maxilla is deficient, and the cleft piriform margin is posteriorly positioned.
- Flaring of the lower lateral cartilage has, depending on the severity of the cleft, variably increased the angle between the medial and lateral crura.
- The cleft-side columella is foreshortened.

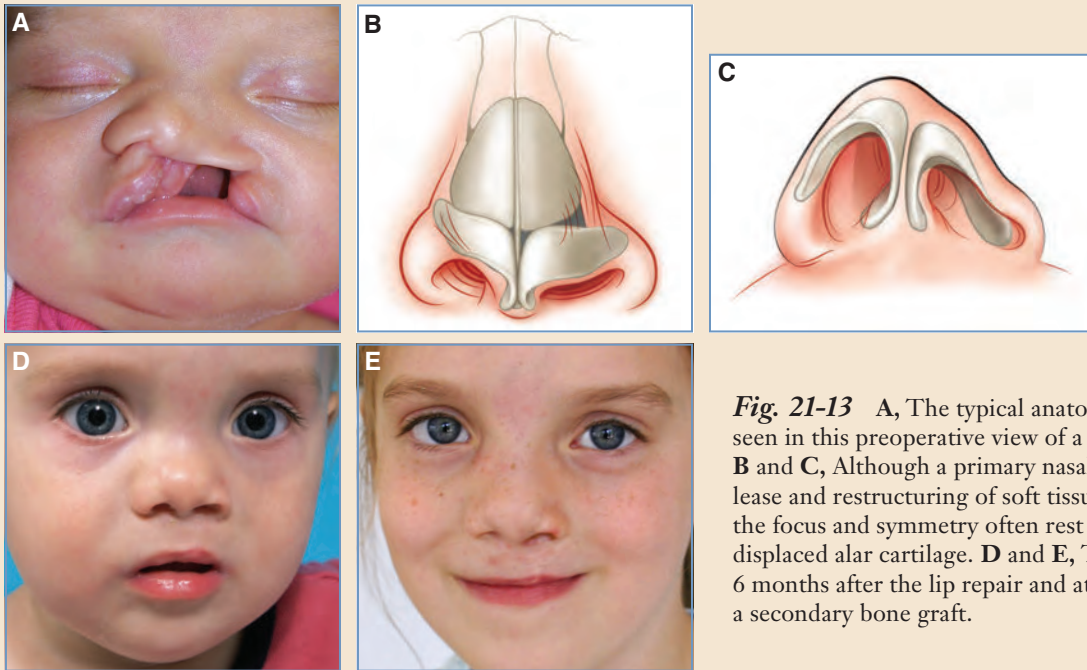

Fig. 21-13 A, The typical anatomic deformities are seen in this preoperative view of a wide unilateral cleft. B and C, Although a primary nasal repair involves release and restructuring of soft tissue and skeletal tissue, the focus and symmetry often rest on correction of the displaced alar cartilage. D and E, The patient is seen 6 months after the lip repair and at 6 years of age, before a secondary bone graft.

Fig. 21-14 A, This patient had a wide unilateral cleft lip and palate with a nasal deformity. B, Seven months after repair of the lip and primary nasal deformity, minor residual asymmetry of the nose persisted. C and D, By 6 years of age, no additional nasal repair has been performed, though she had a primary bone graft at 8 months of age. With growth the nasal symmetry has improved further.

The structural anomalies listed previously lead to the following external characteristics, which provide the stigmata of a unilateral cleft nose:

- The base of the columella deviates to the noncleft side.
- The cleft-side dome is retrodisplaced.
- The cleft-side nostril margin buckles inward.
- The cleft-side ala is flared laterally.
- The cleft-side alar base is posteriorly displaced.
- The interior cleft-side nostril is bowed by a vestibular web (linear contracture) from the apex to the piriform rim.
- The caudal septum rests within the non-cleft side nostril.

These characteristics can be corrected in a primary lip and nose repair to varying degrees depending on the severity of the deformity, the procedure chosen, and the skill of the surgeon. Our practice is to fully elevate the nasal skin off of the underlying cartilaginous structure and reposition it over the columella and ala. The lower lateral cartilage and its associated accessory cartilages are repositioned by dividing the anomalous connection of the lateral crus to the displaced piriform margin. The internal mucosal lining is lengthened with inset of the L-flap, allowing the alar base to descend into a more anatomically appropriate position. These steps improve alar symmetry to the noncleft side. Using quilting sutures along the alar crease, the nasal envelope and soft tissues are redraped in a way that reduces tension on the accessory cartilages and reduces the chance of relapse. These also improve the stereotypical bowing of the cleft-side ala and aid in the inset of the mucosal L-flap, if it has been used.

We think the most important part of the procedure is to ensure the soft tissues are released sufficiently to allow symmetrical placement of the alar base and to provide adequate lining to prevent later contracture. The practice of repositioning the caudal septum to help centralize the columella has been variously described.¹⁷⁻²¹ For some, it is a matter of routine to perform this as part of the primary repair of the lip and nose. It has been established that this does not restrict future growth of the nose or midface. It is not our standard practice in routine cases, but it may be beneficial in cases in which the width of the cleft or the deviation of the columellar base prevents tension-free approximation of the muscle (see Figs. 21-13 and 21-14).

Unilateral Cleft Nasal Deformity: Intermediate Repair

Primary rhinoplasty–intermediate repair is performed for residual cleft nasal deformity after the primary lip and nose repair and before the definitive rhinoplasty.^{18,22-24} Achievable goals include the following:

- The columellar base is centralized.
- The alar base is symmetrically positioned in the craniocaudal plane.
- The nostril margin is repaired to match the size and orientation of the non-cleft nostril.
- The lower lateral cartilage–accessory cartilage complex is further released from the lateral piriform margin.
- The vestibular web is released and repositioned using a right-angle Z-plasty (Fig. 21-15).
- Anteromedial advancement of the cleft-side lateral crus and dome
- A normal scroll area is created.

The corrections are limited, because the underlying skeletal deficiency is not corrected until the nasal base and piriform cleft are bone grafted. Once this is done, the definitive septorhinoplasty can be performed.

Occasionally, a primary repair was effectively performed, but either the L-flap was of inadequate size or secondary scar contracture along the nasal sidewall created a web that placed traction on the ala and flattened the nostril. This deformity can usually be addressed with a right-angle Z-plasty as early as the palate repair, possibly preventing an additional procedure when the child is of school age (see Fig. 21-15). The mainstay of our intermediate repair for unilateral cleft nasal deformity, however, is the repair described by Tajima and Maruyama,²³ which we modified and reported on in 1980.²⁴ The approach is directed at the nasal tip but can be combined with secondary repairs²⁴ (Fig. 21-16). Tajima and Maruyama's original description is modified primarily in the use of a cleft lip nasal retractor for placement of the supporting sutures to lift and reshape the displaced ala (Fig. 21-16).

Fig. 21-15 A, The caudal displacement and flattening of the ala in this case appeared to be secondary to inadequate release and repositioning of the alar cartilage during the primary nasal repair. B, However, an inspection revealed a vertical alar web along the line of the inset L-flap. C, Release of the web with a right-angle Z-plasty repair allowed the ala to assume its normal position without additional suspension.

Fig. 21-16 The Tajima repair. A, With gentle pressure on the ala, the nostril is elevated and the position of the reverse-U incision is marked symmetrically with the non-cleft side.

Continued

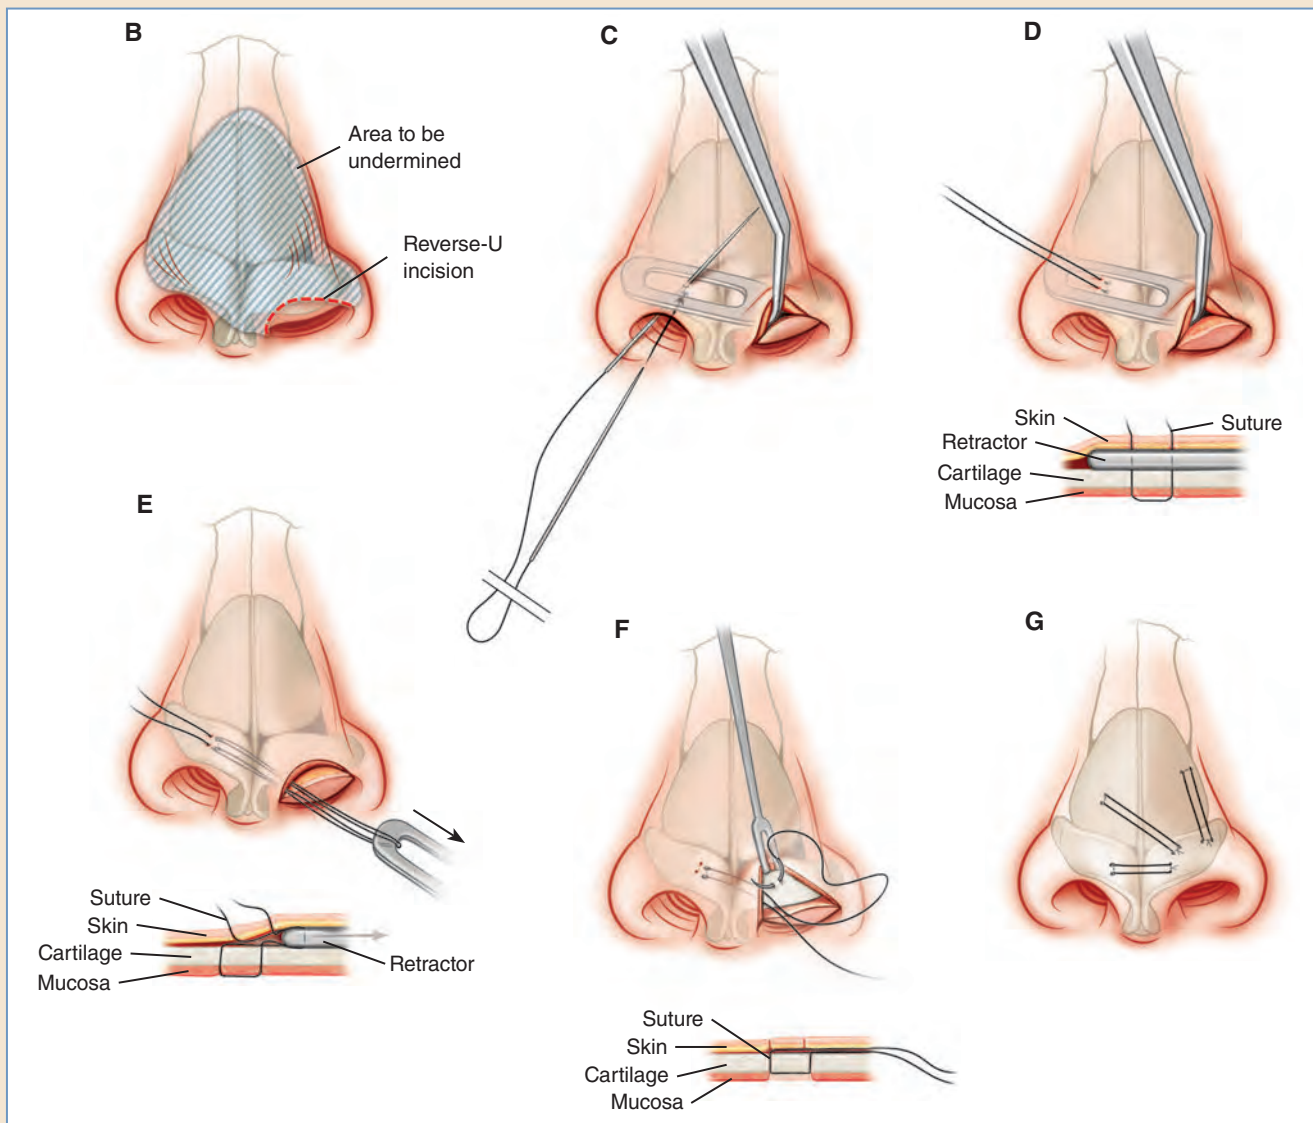

Fig. 21-16, cont'd B-F, A cleft nasal retractor is used for placing the suspending sutures, as shown in K-O. The skin is widely undermined, freeing the skin envelope from the underlying cartilage. The cleft nasal retractor is used to position the sutures for suspension of the displaced cartilage. The cleft retractor is placed between the cartilage and skin, and the sutures are passed with a straight needle through the mucosa, cartilage, retractor, and skin. The other end of the suture is passed in a similar fashion, starting 3 to 4 mm from the first one. The retractor is withdrawn and the free ends of the suture passed back through the skin and through the incision. One end is ready for placement through the cleft-side alar cartilage. G, The three suspending sutures used in a unilateral cleft nasal repair.

Fig. 21-16, cont'd H-J, The displaced cartilage is gently elevated, and the incision is outlined. The orientation of the incision is shown in three views. K, The skin envelope is freed extensively from over the upper and the lower lateral cartilages bilaterally. L-N, Clear nylon sutures are passed through upper lateral cartilage on the contralateral and ipsilateral sides and through the contralateral dome using the cleft retractor, as illustrated in B-F. O, Each of the three sutures is passed through the cleft alar cartilage: from the ipsilateral upper lateral cartilage to the lateral cleft ala, from the contralateral upper lateral cartilage to just lateral to the dome of the cleft ala, and from dome to dome. P, The sutures are tied, stopping each at the symmetrical position to the normal side. The extra tissue gained with the initial flap outline moves inward to provide the additional lining tissue. Q and R, The final correction.

Modified Tajima Reverse-U Repair

For minor deformities, we prefer to await facial skeletal growth and alveolar bone grafting for a definitive septorhinoplasty. Often, however, deformities of the soft tissues and the cartilaginous tip are significant, and patients can greatly benefit from earlier correction. Our timing relies on the severity of the deformity and personal social awareness of the patient. Typically, we perform primary repair using a modified Tajima approach^{23,24} (see Fig. 21-16) as early as 4 to 6 years of age.

An alar rim incision is planned by pushing gently on the cleft-side alar base to elevate the nostril. A reverse-U incision is planned at a location symmetrical with the non-cleft side nostril peak (see Fig. 21-16, *A*, and *H* through *J*). The incision starts at the membranous septum, curving slightly over the nostril rim, parallel to the cartilaginous dome, then reentering the nose, curving downward to end lateral to the fold in the nasal vestibule. The cartilage is identified and freed from the overlying skin, and a wide dissection is carried over the cartilaginous framework of the nose (see Fig. 21-16, *K*). Three 4-0 clear nylon sutures are passed through the bilateral upper and contralateral lower lateral cartilages and tagged (see Fig. 21-16, *B* through *F*, and *L* through *N*). This is facilitated by the use of a cleft nasal retractor inserted below the nasal envelope. The suture ends are passed through the mucosa, the cartilage, and the retractor (a modified Senn retractor with the tip drilled to allow passage of a Keith needle and suture) and then out the nasal skin using straight Keith needles. The suture ends are brought out of the alar rim incisions and then passed, using a curved, free needle, into sequential sections of the cleft-side lower lateral cartilage (see Fig. 21-16, *B* through *F*, and *O*). The sutures are then tied (see Fig. 21-16, *P*) simultaneously, ensuring proper tension to elevate the cartilaginous dome into an anatomic position (see Fig. 21-16, *Q* and *R*). Often, a slight excess of nostril skin is present on the mucocartilaginous cutaneous flap. This can be judiciously trimmed for a meticulous inset. The skin is closed with interrupted 6-0 chromic gut sutures and two or three quilting sutures along the alar crease.

Bilateral Cleft Nasal Deformity

Historically, bilateral nasal deformities were reconstructed in staged fashion using tissues recruited from the labial elements. In the early 1990s McComb²⁵ spearheaded an about-face movement to reconstruct the nose at the time of primary lip repair by bringing tissue from the nasal domes into the columella for bilateral defects. Since then, the technique has been refined and various presurgical orthopedic devices introduced to aid in positioning of the premaxilla, prolabium, and nasal domes.^{18,19,26,27} These devices are discussed in more detail in chapters addressing primary lip repair (see Chapters 19 and 20).

The anatomy of a bilateral cleft lip nasal deformity is not merely a duplication of the unilateral cleft deformity. The deformity has the following characteristics:

- The alar domes and medial crura of the lower lateral cartilages are splayed and caudally rotated.
- The superior columella is spread into the nasal tip by the laterally displaced and flattened medial crura.
- The lateral crura are positioned posteriorly along the deficient piriform margin.
- Excess fibrofatty tissue is interposed between the cartilaginous alar domes.
- The scroll area is missing, because the lower lateral cartilages are splayed laterally, away from a position overlapping the caudal upper lateral cartilages.

These structural anomalies lead to the following external characteristics of bilateral cleft nasal deformities:

- A broad, flat nasal tip
- A short columella
- An obtuse columellar-labial angle

- A blunted scroll area
- A nostril shape that is often slumped, with buckling of the alar margin and a widely splayed alar base

Repair of the Bilateral Cleft Nasal Deformity Using a Bilateral, Modified Tajima Reverse-U Technique in Primary Repair

The guiding principle in the primary repair of a bilateral cleft nasal deformity is to recognize that primary repositioning of the lower alar cartilages will reconstruct the nasal tip and columella. Our technique involves degloving the skin envelope of the nose during the primary lip repair and releasing the investing perichondrium of the lower lateral cartilages and their accessory cartilages from the insertion along the piriform margin. As in a unilateral cleft nasal repair, this allows re-draping of the skin once the cartilages are properly aligned. After repair of the lip, alar rim incisions are made at the prospective new apex of the nostril with a reverse-U pattern (Fig. 21-17, *A* through *E*). This varies from a unilateral Tajima technique in that the apex of the reverse-U shape should be more medially oriented to ensure a more natural tapering of the upper columella^{23,24} (Fig. 21-17, *E*). The nose is dissected until the lower lateral cartilages are identified and fully released from the overlying skin envelope. Often, the excess fibrofatty tissue needs to be thinned or removed to fully approximate the domes. Mattress sutures are placed at the medial crura and

Fig. 21-17 A modified Tajima repair used for a primary bilateral cleft lip and nose. **A**, The outline of the lip incisions. **B** and **C**, An optimal repair requires adequate release of the lip and the displaced alar bases in the dissection and lining of the lateral nasal defects to ensure the final alar base positioning is not restricted. **D**, The lip repair is completed. At this stage, the columella is short, and the alar cartilages are still displaced. **E**, The reverse-U incisions are skewed more medially than in unilateral cases so that on completion of the repair, the columella tapers naturally.

Continued

Fig. 21-17, cont'd F-H, At the completion of the repair, the columella is lengthened. Note that the columellar-labial angle is well defined.

between the domes to bring the lower lateral cartilages into the proper position. Typically, this simultaneously redefines the scroll area. However, if the superiormost aspect of the lower lateral cartilages remains caudally displaced, mattress sutures are placed connecting the lower margin of the upper lateral cartilages to the lower lateral cartilages to elevate the tip appropriately. Once this is complete, there may be a small segment of skin on the reverse-U flap. This should be judiciously trimmed at the region of the soft triangles. Although this excision is often performed in bilateral Tajima repairs, it is rare in unilateral procedures. Overexcision can result in a thin and peaked alar margin that is very difficult to correct in future reconstructions. Quilting 6-0 chromic gut sutures are placed along the alar crease to set the skin envelope properly. Finally, a 5-0 chromic gut mattress suture is placed behind the columella to secure the mucosal flaps. The tissue gained with this approach results in a columella of normal proportion with a well-defined columellar-labial angle (Fig. 21-17, *F* through *H*).

Bilateral Cleft Nasal Deformity: Intermediate Repair

In cases in which the primary repair does not address the nasal deformity beyond the limited amount accomplished with the repair concentrated on the lip, the columella is short, the medial crura are placed under tension, the domes are flattened, and the tip is collapsed. This dramatically worsens the nasal deformity. A bilateral, Tajima reverse-U technique, previously described, can be used as an early nasal repair (Fig. 21-18). Early repair has several benefits. It improves the appearance of the nose and opens the external alar valves, which can be quite obstructed in this instance. The incisions lend themselves to the definitive open rhinoplasty. An early intermediate repair can also be used to better define the nasolabial angle. Finally, a chonchal tip graft can help to further refine the tip if intradomal mattress sutures fail to do so (Fig. 21-19). At the definitive repair, this extra cartilage often aids the surgeon by providing added cartilaginous tissue to support tip sutures or to smooth strut grafts. The main differences between a unilateral and a bilateral modified Tajima repair used as an intermediate repair and a repair carried out primarily is the orientation of the reverse-U incision (angled medially in bilateral cases) and the number of sutures placed (see Figs. 21-16 *A, I*, and *J*, 21-17, *E*, and 21-19, *B*).

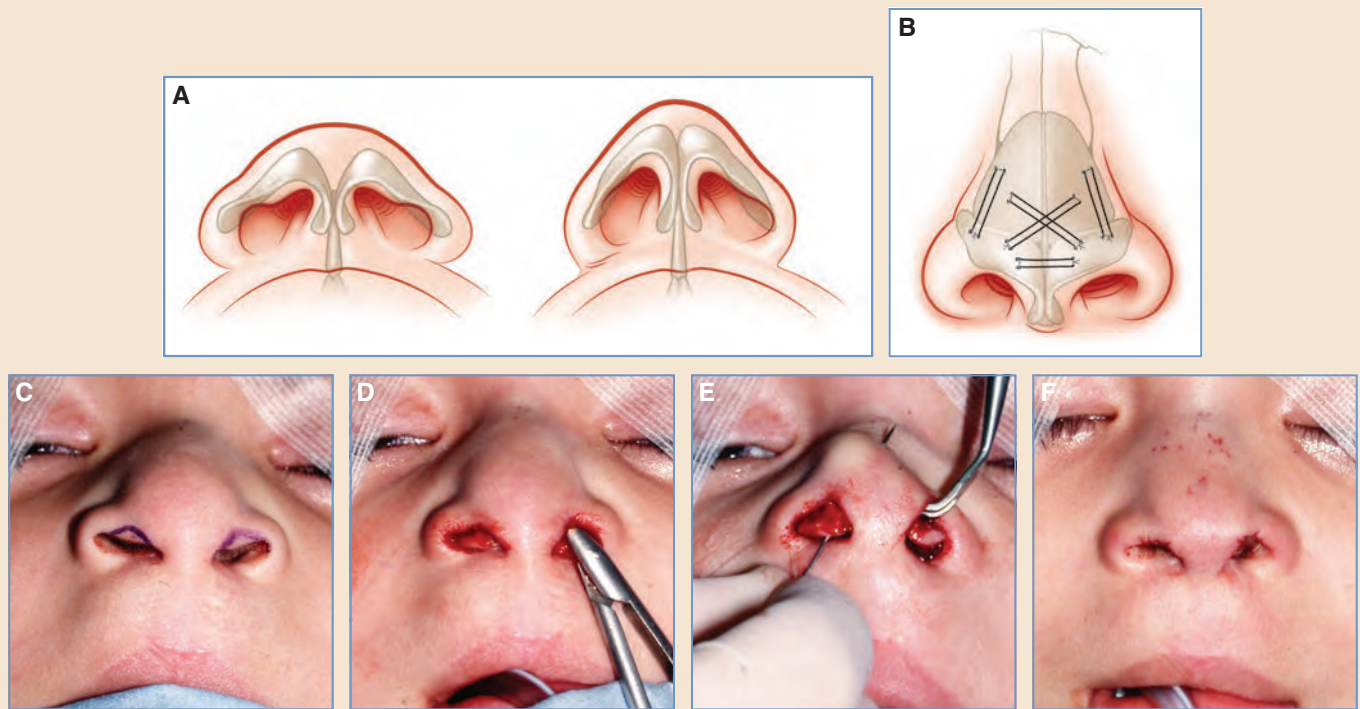

Fig. 21-18 The application of the bilateral Tajima repair in early secondary correction. **A**, The difference in orientation of the alar cartilages between an uncorrected bilateral cleft nose and a normal nose. **B**, The position of the suspending sutures. **C**, The incisions in this case are more typical of those used in a unilateral case; that is, they are not skewed medially. **D**, The wide undermining of the soft tissue envelope off the cartilages. **E**, Suspending sutures are passed using a cleft nasal retractor. **F**, The reshaped tip after tightening of the sutures and closure.

Fig. 21-19 In selected cases, the nasal tip shape and projection can be augmented with a conchal cartilage graft placed just above the domes of the alar cartilages as they are approximated. **A**, A preoperative view shows the broad, flat nasal tip. **B**, Incisions taper superiorly, as described previously, and conchal cartilage is shaped for placement. **C**, The completed repair.

The supporting sutures pass from the lateral lower lateral cartilage to the ipsilateral upper lateral cartilage, from the lower lateral cartilage just lateral to the dome to the contralateral upper lateral cartilage, from dome to dome, and from medial crura to medial crura. The passage of these sutures is facilitated with a cleft nasal retractor. As the sutures are tied, the nostril changes orientation from horizontal to oblique, the columella tapers, and the nasolabial angle sharpens. This change of orientation helps to gain the additional columellar length, from the nose rather than the lip, which results in the need for minor trimming of the skin of the reverse-U flaps.

Secondary Cleft Nasal Deformities

The goals of secondary cleft rhinoplasty are to create a symmetrical, normal- and natural-looking nose from the top down and to optimize nasal breathing and function. Although primary cleft rhinoplasty can do much to achieve a more normal-looking nose, the limitations in dissection and bony and septal work can lead to secondary deformity as a patient enters the teenage years.

Description of Secondary Cleft Nasal Deformities

Secondary cleft deformities occur in all shapes and sizes, but the general deformity is fairly uniform and includes the following:

- Skeletal deficiency of the alar base
- Nasal bone pyramid asymmetry and excess width
- Nasal tip asymmetry, with shortening, flattening, and malposition of the affected side lower medial and lateral cartilages (see Fig. 21- 18, *B*, and *D* through *F*)
- Alar base soft tissue asymmetry/deformity
- A thick skin/soft tissue envelope
- Septal deviation

Myriad associated iatrogenic deformities can be present depending on the type of primary repair performed.^{2,21-25}

Septorhinoplasty in the Cleft Patient

The timing of secondary rhinoplasty and septoplasty in cleft nasal patients varies, but these procedures are typically performed when patients are teenagers. We do not rely on a single standard age for repair, but instead usually rely on the following guidelines^{28,29}:

1. The patient is at least 1 year postmenarcheal.
2. Growth has not been significant over the past 1 to 2 years, as documented by the patient's pediatrician.
3. The patient's parents are ready for the patient to proceed with surgery.

These guidelines have been shown to produce consistent, lasting results, establishing that there is no single, set age at which rhinoplasty can be safely performed. We will perform septorhinoplasty even earlier, in the preteen and early teen years, if the deformity is severe enough to cause significant psychological detriment.

During cleft nasal and septal surgery, surgeons may encounter both natural and iatrogenic deformities. Every nose has a slightly different (if not majorly different) morphology. Therefore, for all deformities, surgeons should focus on deconstructing the nasal tip and doing whatever is required to make it look normal and then complete the dorsal and bony work (Fig. 21-20). This is accomplished through soft tissue release, repositioning of the native structures, suture techniques, and cartilage grafting. The same principle applies to the septum. The tip or septum should be completely replaced and rebuilt if the deformities are too severe to salvage.

Fig. 21-20 A, An ideal medial and lateral crural tip shape. B, Distorted shape and position of cartilages in a unilateral cleft nose.

Surgical Technique

Details for each of the operative steps are listed below, but the major overview concepts include septoplasty/septal reconstruction, alar base augmentation, reconstruction of the nasal tip cartilages and lengthening of the columella, evening and narrowing of the nasal bones, creating the ideal dorsal profile, and creating a more symmetrical alar base, combined with any necessary alar soft tissue excision techniques. The sequence of these steps may be debated, but the most consistent and logical order is as follows:

1. The nose is opened, and the nasal tip is deconstructed.
2. Septoplasty/septal reconstruction is performed.
3. The columella is lengthened, and the tip is reconstructed and stabilized.
4. The dorsal profile is refined to match the tip position.
5. Osteotomies are completed.
6. The alar base and tip soft tissue are refined.

Septoplasty

Septoplasty is performed through an open approach in cleft patients. The septal mucosal flaps can be easily elevated starting at the caudal end of the septum, between the medial crural cartilages of the tip (Fig. 21-21). Once the upper lateral cartilages are separated from the septum, the entire septum can be visualized using a nasal speculum. This is especially useful with severe or complicated deviations that require careful elevation of the mucosal flaps to prevent rents and tears.

Fig. 21-21 The septum is often most easily accessible after the anterior septal angle is identified.

With the entire septum visualized, a portion of the posterior quadrangular cartilage can be excised. (A No. 15 blade is much preferred over a swivel knife.) All posterior bony septal deviations can be directly excised. A dorsal and caudal portion of the septum will remain, which should ideally be at least 1 cm wide (or more if a dorsal hump takedown is planned), thus creating a stable L-strut.

Remaining septal deflections, whether caudal or dorsal, may require further steps to ensure they are completely straight. Curvatures of the dorsal septum create asymmetry of the brow-tip aesthetic lines on an AP view, a severely canted dorsal septum can lead to a persistently crooked nose, and residual caudal deflections can lead to airway obstruction. Options for correction include the following³⁰:

1. Scoring on the concave side to curve the cartilage away from the scored side
2. Castellation of a dorsal strut from above and below (vertically incising the septum yet keeping it intact)
3. The placement of upper lateral cartilage-to-septal transfixion sutures
4. The placement of a cartilaginous spreader graft on the concave side of the septum
5. The placement of dorsal onlay graft to camouflage the curve
6. Total or subtotal resection of the deformed septum and reconstruction with a septal or rib cartilage graft or grafts

We tend to rely heavily on subtotal and total reconstruction of the deformed septum to ensure a straight and consistent result, which has reduced the revision rate. Remaining caudal septal deflections require a swinging-door approach, which entails completely releasing the caudal septal base from the underlying maxilla, excising a 1 mm portion if necessary, repositioning the base over the direct midline maxillary crest, and fixing it in place with mattress sutures.

Tip Reconstruction

No matter what deformities are encountered during cleft rhinoplasty surgery, the goal should be to do whatever it takes to make the tip structures look normal.⁴ We start by reconstructing the tip to achieve three ideal, major nasal parameters: length, projection, and rotation of the tip.^{22,24,31-35} A superbly harmonious result requires ensuring the major nasal parameters are achieved and set in the desired position before addressing the remaining nasal issues. The dorsum can then be tailored to fit these parameters and the fine tip work details completed. We have found that approaching the nose in this manner will guide the surgeon to the most predictably acceptable outcome.³⁶

Using an open approach, we make an inverted-V incision with vertical incisions along either side of the columella. Unlike the standard approach in a noncleft rhinoplasty, the lateral columella incision is extended inferiorly along the anterior edge of the medial crural footplate on the affected side and carried down into the nasal sill (Fig. 21-22). With the nasal flap elevated and the tip cartilages exposed, the supporting ligaments of the tip are released to allow full mobilization of the tip structures. It is easiest to gain access to the septum at this point, and the septoplasty is performed. Once the septoplasty is completed, the medial crural footplate on the affected side is completely freed and advanced upward to meet the ideal position of the dome on the nonaffected side. This rotation-advancement flap of cartilage and mucosa is critical to ensure tip symmetry and a consistent, long-lasting result.

With the columellar base reasonably exposed, the alar base can be augmented. We typically use harvested septal or rib cartilage³⁷⁻⁴¹ and place the graft through a precise pocket exposed through the access provided once the medial footplate has been released. The broad, amorphous tip is then addressed. Cephalic trim and evening of the lower lateral cartilages are performed. A double hook is used (with one tong under each dome and using the instrument to stabilize the tip position) to set the ideal length, projection, and rotation. A columellar strut is placed to stabilize the ideal nasal tip parameters and to set the dome position securely (Fig. 21-23). The ideal dome position is then marked. Intradomal (single-dome-unit binding) sutures are placed using 5-0 or 6-0 permanent suture.

Fig. 21-22 Unlike the standard approach in a noncleft rhinoplasty, the lateral columella incision is extended inferiorly along the anterior edge of the medial crural footplate on the affected side and carried down into the nasal sill.

Fig. 21-23 A double hook is used to set the ideal length, projection, and rotation. (One tong is placed under each dome, and the instrument is used to stabilize the tip position.) A columellar strut is placed to stabilize the ideal nasal tip parameters and to set the dome position securely.

With the columellar base and tip stabilized, the surgeon can examine and reconstruct the lower lateral cartilages for symmetry and shape. This almost always requires bilateral lateral crural strut grafts to be placed. Lateral crural strut grafts will even the lower lateral cartilages and reduce the convexity (bulbosity), thereby creating an ideal normal shape. The strut grafts will provide long-term stability to the repair. The mucosa is dissected free from the undersurface of the lower lateral cartilages. On the nonaffected side, the strut graft is placed beneath the native lower lateral cartilage and secured. With a unilateral cleft deformity, the lower lateral cartilage attachment laterally to the soft tissues is asymmetric. Therefore, on the affected side, the lateral lower lateral cartilage is completely released from its soft tissue attachments, an extended alar strut graft is placed, and the lateral end of the extended alar strut graft is placed into a new, more caudal position by dissecting a new pocket and fixating the graft over the piriform aperture. This may also be required on the nonaffected side to even the alar rim positions bilaterally. The entire tip complex looks normal and symmetrical, and tip cartilage grafting can be performed to achieve the ideal projection and tip shape at the domes. Not every patient requires tip grafting. It should be done only when necessary to prevent overprojection or an abnormal, grafted-tip appearance. The length, projection, and rotation have been set. The dorsal profile can be set to the ideally positioned tip.

Correction of a short, overly rotated nose in a bilateral cleft patient typically requires rib cartilage grafting and nasal lengthening.⁴² The nose can be lengthened by infratip lobule grafting or by augmenting the nasofrontal region. More severe cases may require bilateral extension spreader grafts with a columellar strut graft or caudal septal extension grafts. Dorsal augmentation in cases of saddlenose deformity produces apparent lengthening and will result in a more aesthetically pleasing, straight dorsal profile.

Dorsum Techniques

At this point, the tip should be symmetrical with a normal appearance. It is time to match the dorsal profile and appearance to the tip. The nasal dorsum requires a tremendous amount of judgment in rhinoplasty. The nasal dorsum comprises the middle vault (cartilaginous) and the upper nasal vault (osseous). Pollybeak deformities are either cartilaginous or secondary to soft tissue excess and should be corrected to achieve a straight dorsal profile. The osseous vault requires osteotomies. Additional deformities anywhere along the dorsal length (that is, open-roof deformities and upper lateral cartilage contour deformities) require correction. Bilateral cleft deformities may require central onlay dorsal augmentation grafting. As stated previously, no matter the deformity, the goal should be to undertake whatever maneuvers are necessary to straighten the dorsum.

In patients with dorsal fullness, creating a straight dorsal profile requires leveling the bone, the bony/cartilaginous junction (rhinion), the dorsal cartilaginous septum (pollybeak), or all three. The bone is rasped, starting with a more coarse rasp, followed by finer rasps. The cartilaginous pollybeak is corrected by leveling the dorsal quadrangular cartilage to a favorable profile using sharp straight scissors or a No. 11 blade. The dorsum is augmented with cartilage grafting, either using septal cartilage (single or stacked) for smaller concavity deformities or rib cartilage for more severe deformities requiring a thicker graft. Spreader grafts set above the profile of the dorsal cartilage can be used to augment the dorsum through the middle third.

Nasal bone anatomy is quite variable. Some patients have short nasal bones; others have long nasal bones. Younger patients tend to have very thick nasal bones. Regardless of the nasal bone

Fig. 21-24 Nasal bone osteotomies. **A**, Medial osteotomies are performed first, with care not to disrupt the septal–nasal bone junction. **B**, Lateral osteotomies are started superior to the inferior turbinate and performed in a high-low-high fashion. An osteotome can be used as a lever to assist in making a greenstick fracture of the nasal bone medially.

anatomy, medial and lateral osteotomies are required to narrow the upper third and straighten the nose.^{43,44} We use guarded straight and curved osteotomes. A medial osteotomy is performed first, starting at the caudal end of the nasal bone, between the septum and upper lateral cartilage on each side. The osteotomy should be faded and curved laterally as it is continued cephalad, preventing a rocker deformity. Lateral osteotomies are then performed, using an internal approach, with the osteotomy starting just above the head of the inferior turbinate, along the lateral nasal wall. A high-low-high osteotomy is thus effected. The medial and lateral osteotomies are not joined, but rather the lateral osteotomy is brought just medial to the medial canthus, and a greenstick fracture is produced using the force of the osteotome to create an infracture. A greenstick fracture will result in a much more stable fracture site without excessive bony instability (Fig. 21-24). Spreader/spacer grafting is then performed as needed to ensure straightness of the nose on an AP view and/or to correct internal nasal valve dysfunction. The upper lateral cartilages are finally secured back to the midline using an absorbable suture.

The overall underlying structures should be straight and ideally positioned. Concavities or irregular depressions can be evident anywhere along the dorsum and/or tip. Often, dorsal irregularities need to be camouflaged with onlay grafting using cartilage, soft tissue, or fascia. Cartilage grafts should be thin and beveled as much as possible so that they do not show through thin skin once the edema resolves and to prevent secondary step-off deformities. These grafts can be secured directly to the underlying skeleton framework, or they can be secured more precisely using transcutaneous sutures, which can be left in place for 4 to 7 days without external scarring.

Fig. 21-25 **A**, Sill excision for external base width reduction only. An inverted-V excision is used to decrease the alar base width without changing the nostril circumference. **B**, Sill excision for nostril diameter change only. A V excision is made to decrease the nostril circumference without changing the base width distance. **C**, Sill excision for combined alar base width reduction and nostril diameter reduction. **D**, Alar flare reduction. A portion of the lateral alar base is excised to decrease the tip-alar facial groove distance.

Alar Base Soft Tissue Techniques

Once the overall major parameters of the tip, the fine structural tip detail, and the nasal dorsum have been optimized, the nasal tip soft tissues are evaluated and treated. The following features are evaluated and treated (Fig. 21-25):

- The alar base width
- Nostril diameter and symmetry
- The alar flare
- Alar hooding
- Alar retraction
- A thickened skin-soft tissue envelope

Alar Base Reduction

Understanding that the ala has a cutaneous surface and a vestibular surface is essential. This helps to maintain or narrow the width of the alar base and to maintain or narrow the nostril size separately in well-controlled fashion. We prefer to use the terms *external alar base reduction* and *internal alar base reduction* to distinguish between the two different surface reductions (alar base width and nostril diameter, respectively). An external alar base reduction is performed to reduce the columellar-alar base distance, thereby reducing the apparent width of the lower third of the nose on AP and basal views. An internal alar base reduction is performed to narrow the nostril circumference (vestibular surface).

An alar base reduction is best performed in the nasal sill. Not disrupting the natural curve of the alar base is critical. If only an external reduction is planned (to reduce the columellar-alar width), the appropriate estimation of resection is planned and marked along the upper and lower portion of the nasal sill, and the excision is performed. The excision is wide at the bottom of the sill and tapered in an inverted-V pattern to address only the external reduction without changing the circumference of the nostril. If the nostril circumference needs to be reduced, the excision should not be tapered on the internal edge of the sill, and the appropriate amount of tissue should

be excised.⁴⁵ In most cases of alar base reduction, it is necessary to create a true advancement-rotation flap of the entire alar base to prevent notching, to provide a more natural curve, and to reduce tension along the suture line, thereby optimizing the scar outcome.

Alar Flare Reduction

With a rotation-advancement flap closed with a single suture, alar flaring can be assessed. If necessary, an alar flare reduction is performed. Alar flaring is seen when the lateral aspect of the ala extends significantly beyond the alar-facial groove. If alar flare reduction is indicated, the amount of resection is planned, marked, and excised. The wounds are completely closed with 6-0 nylon. Most of the cutaneous sutures are removed on postoperative day 4, with the exception of the central sill suture and the more cephalad sutures on the inner portion of the sill, which are left in place for 6 days. Steri-Strips are placed for an additional 4 days once the sutures are removed.

Alar Hooding Reduction

Alar hooding is best analyzed from a direct lateral view. It is seen when the most caudal curve of the ala (alar rim) hangs excessively low, either from excessive bulk of the ala or from an excessively caudal alar insertion, thus hooding over the columella and obscuring it from view. If indicated, the resection is planned using a direct lateral view. The visual border of the ideal alar curve is marked, and an ellipse is drawn on the inner portion of the ala that matches the outer visual border. This incision should be planned carefully and should curve gently to prevent distortion of the nasal ala. After the excision, the wound is closed with running 6-0 nylon along the most caudal aspect of the alae. The suture line falls along the visual border, in a natural plane. We have not found healing along this line to be a problem. Sutures are removed on postoperative day 4.

Alar Base Repositioning

If the vertical height of the lip is in balance (that is, if the Cupid's bow is level and the subalar-Cupid's bow peak heights are symmetrical), minor asymmetries of the alar bases in the vertical dimension can be addressed by a Z-plasty. If the alar insertion is too low, reciprocal transposition of the alar base with a triangle taken from cephalad within the nostril sill and vestibule can be helpful; however, care must be taken not to introduce skin of different character (thickness, color, hair, or scar) onto the upper lip (see Fig. 21-2). If the alar insertion is too high, a reciprocal transposition of the alar base with a triangle taken from the upper lip can be performed.

Thickened Skin-Soft Tissue Envelope

Once a nasal flap has been elevated in an open approach, the soft tissue under the flap can be conservatively thinned using sharp scissors. Only the tissue that is excessively hanging should be excised. Excessive thinning of the undersurface of the dermis can lead to ischemia of the flap.

FUNCTIONAL NASAL ISSUES AND TURBINATE CORRECTION

The structural components of the airway comprise the septum, internal nasal valves, external nasal valves, and inferior turbinates, all of which require examination and optimization and can be corrected surgically.⁴⁶ Repair of the nasal septum through septoplasty and spreader graft placement to correct internal nasal valve dysfunction has already been described in this chapter. The external nasal valves will be strengthened and optimized when lateral crural strut grafting is performed to even the tip complex. After these procedures and a rhinoplasty have been performed, enlarged inferior turbinates can be reduced. It is best to reduce the overall size of an inferior turbinate with mucosal reduction outfracture of the bone. Complete excision should be avoided. Our preferred technique is submucous resection of the mucosa using a turbinate debrider with a direct outfracture. Coblation and cautery can also be used (Figs. 21-26 through 21-28).

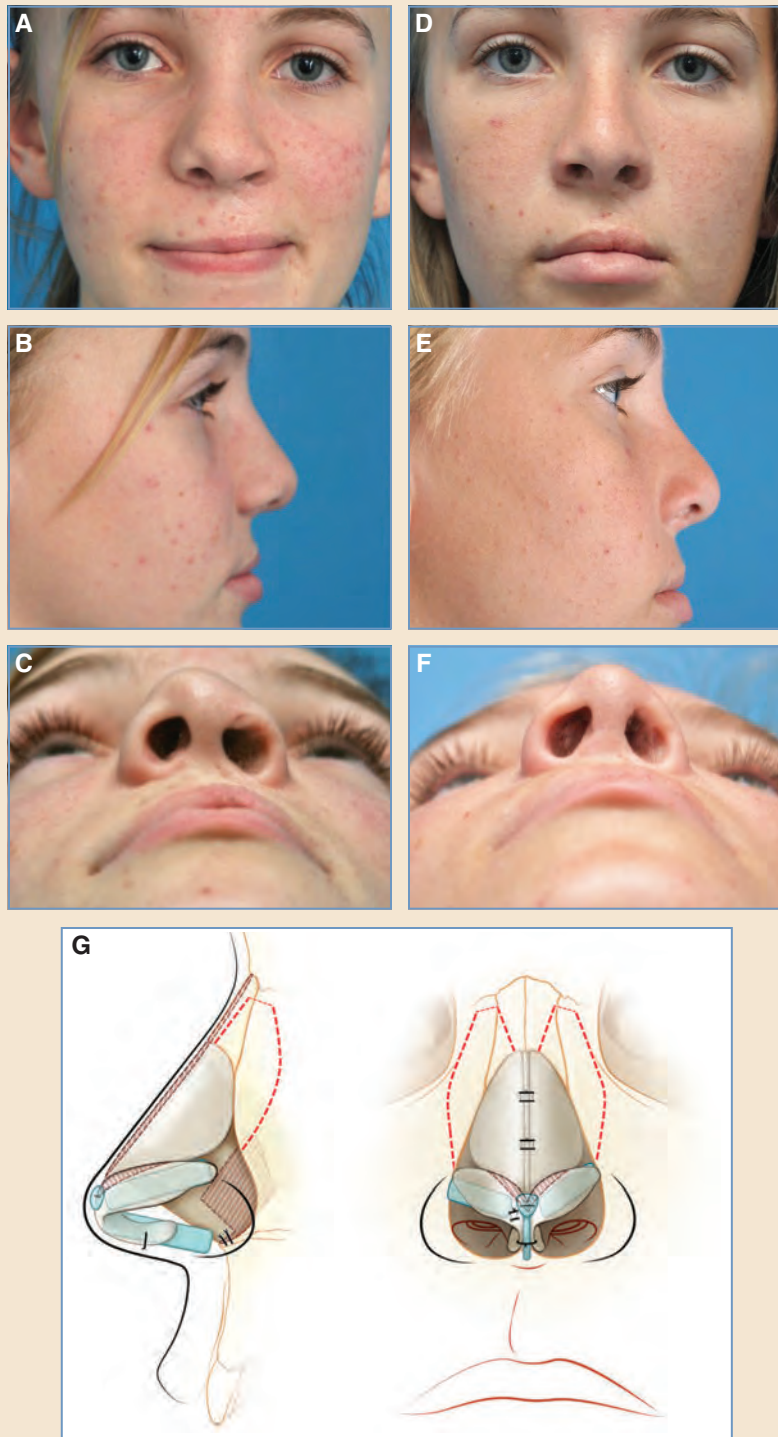

Fig. 21-26 This unilateral cleft patient underwent septorhinoplasty using an open approach with a unilateral extended columellar incision, as described previously. **A-C**, Preoperative views. **D-F**, One-year postoperative views. **G**, Rib graft was harvested, given the paucity of septal cartilage after the previous septoplasty. The caudal septum was repositioned. The tip was reconstructed with bilateral lateral crural strut grafts (the right lateral crus with a strut graft was repositioned inferiorly), a columellar strut, a tip graft, interdomal and intradomal sutures, and cephalic trim. The dorsum was rasped. Bilateral medial and lateral osteotomies were performed.

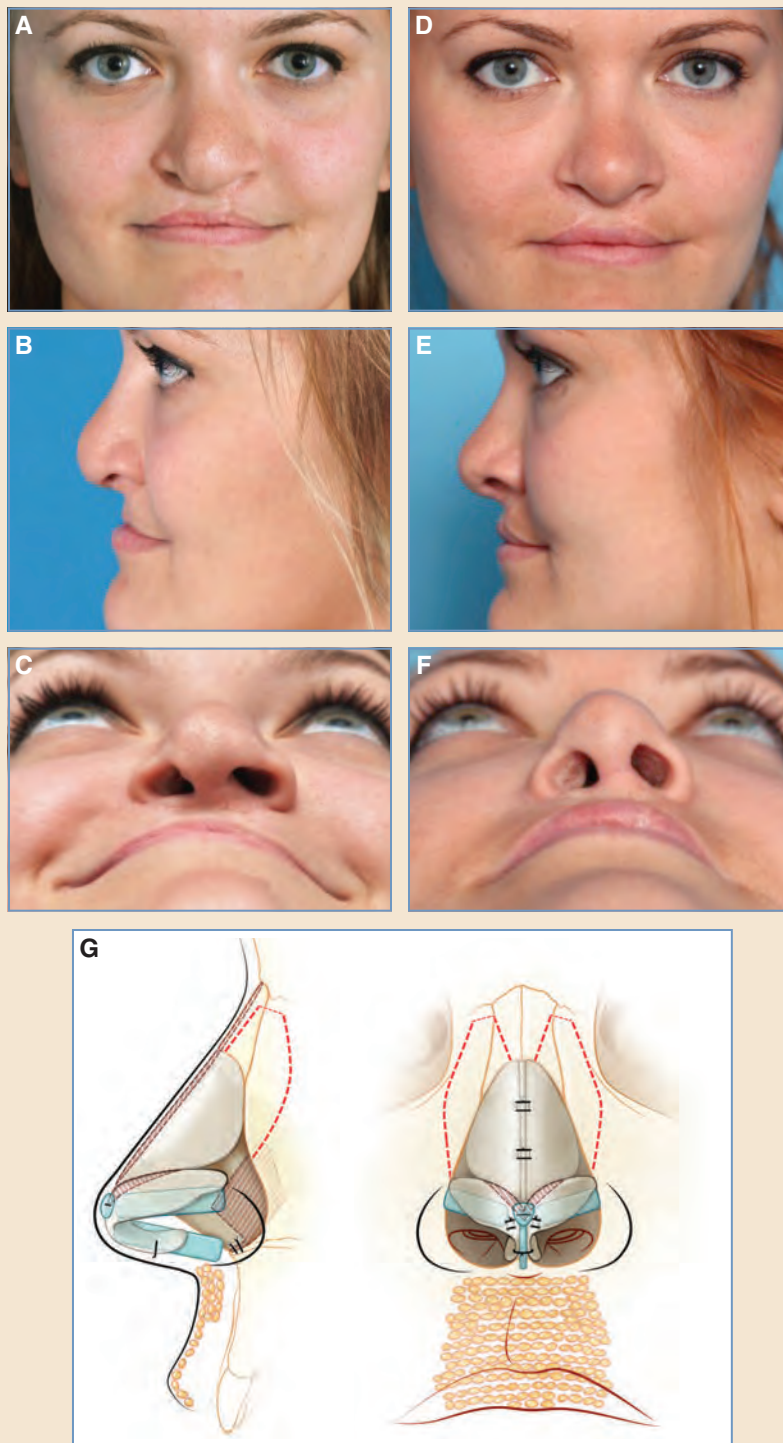

Fig. 21-27 This bilateral cleft patient underwent septorhinoplasty using an open approach with bilateral extended columellar incisions, as described previously. **A-C**, Preoperative views. **D-F**, One-year postoperative views. **G**, A secondary septoplasty with cartilage excision and caudal strut repositioning was performed. Rib graft was harvested, given the lack of native septal cartilage. The tip was reconstructed with bilateral alar strut grafts (both lower lateral cartilage–alar strut grafts were repositioned to a more inferior pocket), a columellar strut, interdomal and intradomal sutures, tip grafting, and cephalic trim. Bilateral medial and lateral osteotomies were performed. Fat was grafted to the nasolabial area and upper lip.

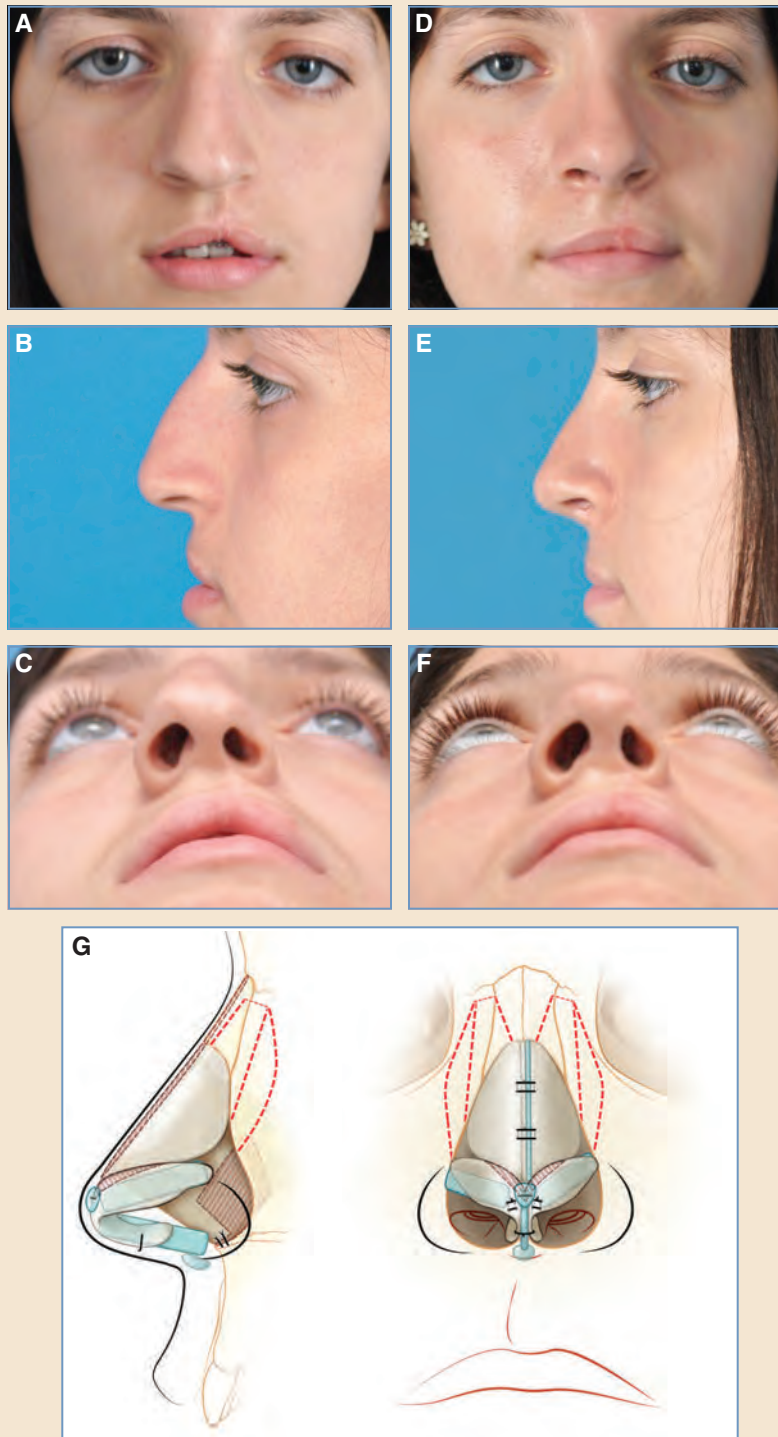

Fig. 21-28 This unilateral cleft patient underwent septorhinoplasty using an open approach with the extended columellar incision described previously. **A-C**, Preoperative views. **D-E**, One-year post-operative views. **G**, Septoplasty was performed with submucous resection and scoring. The tip was reconstructed with bilateral alar strut grafts (the right lower lateral crus was repositioned inferiorly with a strut graft), a columellar strut, tip graft, nasolabial angle graft, interdomal and intradomal sutures, and cephalic trim. The dorsum was rasped. Bilateral medial and double-lateral osteotomies were performed. A spreader graft was placed along the left side.

OTHER CONGENITAL NASAL DEFORMITIES

Other congenital, noncleft-related deformities can occur that may require the techniques discussed in this chapter. Median clefts and dermoid lesions can result in a widened nose, malformed septum, and/or bifid septum. These nonspecific congenital deformities may present myriad challenges. As mentioned previously, regardless of the deformity, rhinoplasty surgeons can use the techniques presented to do whatever is needed to make the nose look normal.

CONCLUSION

The artistry of cleft repair continues to evolve. With the shared experience of centuries of cleft surgery, more aesthetic and functional results can be accomplished with primary lip and nose surgery. However, despite our best efforts to reduce the stigmata of the primary deformity, secondary deformities occur, and secondary correction is usually required. The repair of primary nasal deformities requires patience. A gradual, logical approach directed at staged correction of the primary deformities, without introducing iatrogenic secondary deformities, is encouraged.

KEY POINTS

- Secondary deformities of the lip and nose arise because of limited surgical correction at the initial repair and because key anatomic landmarks were not identified and aligned.
- Although each surgeon has a preferred technique for lip repair, the anatomic subunit principles described by Fisher can be similarly applied to correction of secondary deformities (see Chapter 19).
- Understanding Noordhoff's point and its importance in the design of the lateral vermilion muscular flap to fill a medial vermilion defect is essential to prevent vermilion deficiency and a whistle deformity.
- In all but the very minor forms of unilateral cleft lip, the vermilion below the cleft side of the bow is vertically deficient. If this is not augmented with vermilion from the lateral lip element during the primary repair, a stairstep deformity of the vermilion-mucosal junction (red line) will be present.
- A major cleft lip revision offers an opportunity to reposition a scar to better mirror the noncleft-side philtral column and, for this reason, may be preferable to a minor revision.
- The surgical goals of a major lip revision are similar to those of a primary repair; atypical secondary deformities may need to be addressed using the age-old principles of re-creating the defect and anatomically reconstructing the lip.

Continued

KEY POINTS (continued)

- The degree of secondary nasal deformity depends on the degree of primary nasal deformity and the extent of primary rhinoplasty.
- An analysis of a secondary nasal deformity involves a stepwise assessment of the uncorrected primary deformities.
- The goals of a secondary cleft rhinoplasty are to create a symmetrical, normal- and natural-looking nose and to optimize breathing and function. Although a primary cleft rhinoplasty can do much to achieve a more normal-looking nose, the limitations of dissection and bone and septal work can lead to secondary deformity as a patient enters the teenage years.
- No matter what deformities are encountered during a definitive cleft rhinoplasty, the goal should be to do whatever it takes to make the tip structures look normal.
- A Tajima reverse-U procedure and its modifications can be applied both in primary bilateral cleft lip nasal repair for columellar lengthening and in early and late secondary correction of a unilateral cleft nasal deformity, with the incision placement lending itself well to late, open rhinoplasty.
- A definitive septorhinoplasty should ideally be delayed until skeletal maturity, but earlier correction is warranted in some cases and can be safely performed.
- The most difficult secondary deformities to correct are of iatrogenic origin.

Cleft Palate Deformities

Alexander Margulis • Yair Shachar • Bruce S. Bauer

he existence of a facial cleft in a child requires long-term treatment planning. Because facial clefts affect both function and facial aesthetics, therapy and rehabilitation should begin soon after birth and may continue for many patients until the late teens or early twenties. Although functional effects range from early feeding difficulties to growth attenuation and secondary effects on middle ear function, by far the most significant effect is on speech. The disturbance is typically in the form of *hypernasality* or escape of sound through the nasal cavity on production of many consonants, phonemes, and vowels in the English language. The importance of speech for normal social functioning cannot be underestimated.

Many surgical techniques and modifications have been advocated to improve functional outcome and aesthetic results. The most controversial issues in the management of cleft palate are the timing of surgical intervention, the effects of various surgical procedures on the development of speech, and the effects of surgery on facial growth. We will address these issues in this chapter by reviewing the various techniques and discussing our current preferences and why these procedures are preferred.

EMBRYOLOGY

The primary palate is the keystone to the upper lip and anterior portion of the definitive palate. Its embryogenesis is fundamental to normal development of the midface, and its maldevelopment has profound clinical and sociologic consequences with regard to breathing, sucking, swallowing, mastication, osculation, speech, and facial physiognomy.

Orofacial development in the embryo is first demarcated by the appearance of the prechordal plate at the cranial end of the embryonic disc at postconception day 14.¹ This plate designates the future mouth, or stomodeum. The mesenchyme that provides the facial primordia is oddly of ectodermal derivation, arising from neural crest cells at the apices (crests) of the neural folds

Fig. 22-1 Neural crest origin and migration.

before neural tube formation² (Fig. 22-1). The neural crest cells oddly disrupt the ectodermal-mesodermal boundary and migrate into the subjacent tissue as ectomesenchymal cells. Their migration and proliferation are fundamental to facial development. During their migration they interact with the extracellular matrix and adjacent epithelia, which partly determine the patterning and nature of the derivative tissues they will form. These derivatives include neural, skeletal, connective, and muscular tissues.³ Migration of neural crest cells into the five pharyngeal arches, which they in part create, occurs in a highly regulated manner, under the control of homeobox genes.⁴

The stomodeal chamber, which is the precursor of the future mouth, becomes a deepened central depression in the facial region as a consequence of the surrounding five primordia of the face, bulging at the borders of the stomodeum (Fig. 22-2). The *five primordia* are the single median and rostrally located frontonasal prominence and the paired bilateral maxillary and caudally located mandibular prominences.⁵ These prominences are the result of the migration and mitotic proliferation of neural crest ectomesenchyme, which originates from the caudal region of the mesencephalon and the rhombencephalon of the developing brain. There is also a mesodermal contribution to the mesenchyme of the facial prominences.

Formation of the upper lip involves an extraordinary combination of elements arising from both the frontonasal prominence and maxillary prominence, which are components of the first pharyngeal or mandibular arch. The bilateral medial nasal prominences form the central tuberculum of the upper lip and provide the basis for the primary palate.^{6,7} The upper lip is completed on either side of the central tuberculum by fusion of the freely projecting medial nasal prominences with the laterally located maxillary prominences, requiring critically timed correlation of their growth, spatial location, and disintegration of their contacting surface epithelia that form the transient nasal fin.⁸ Disintegration of the nasal fin by apoptosis or mesenchymal transformation allows intermingling of the underlying mesenchymal cells, providing continuity to the median and lateral components of the upper lip. Failure of normal disintegration of the nasal fin or inadequate mesenchymal migration across the two boundaries of the maxillary medial nasal prominences results in lip clefting, unilaterally or bilaterally, with varying degrees of severity.

Fusion of the medial nasal and maxillary prominences not only provides continuity of the upper jaw and lip but also separates the nasal pits from the stomodeum. The central median component of the face forms the tuberculum and philtrum of the upper lip, the tip of the nose, and

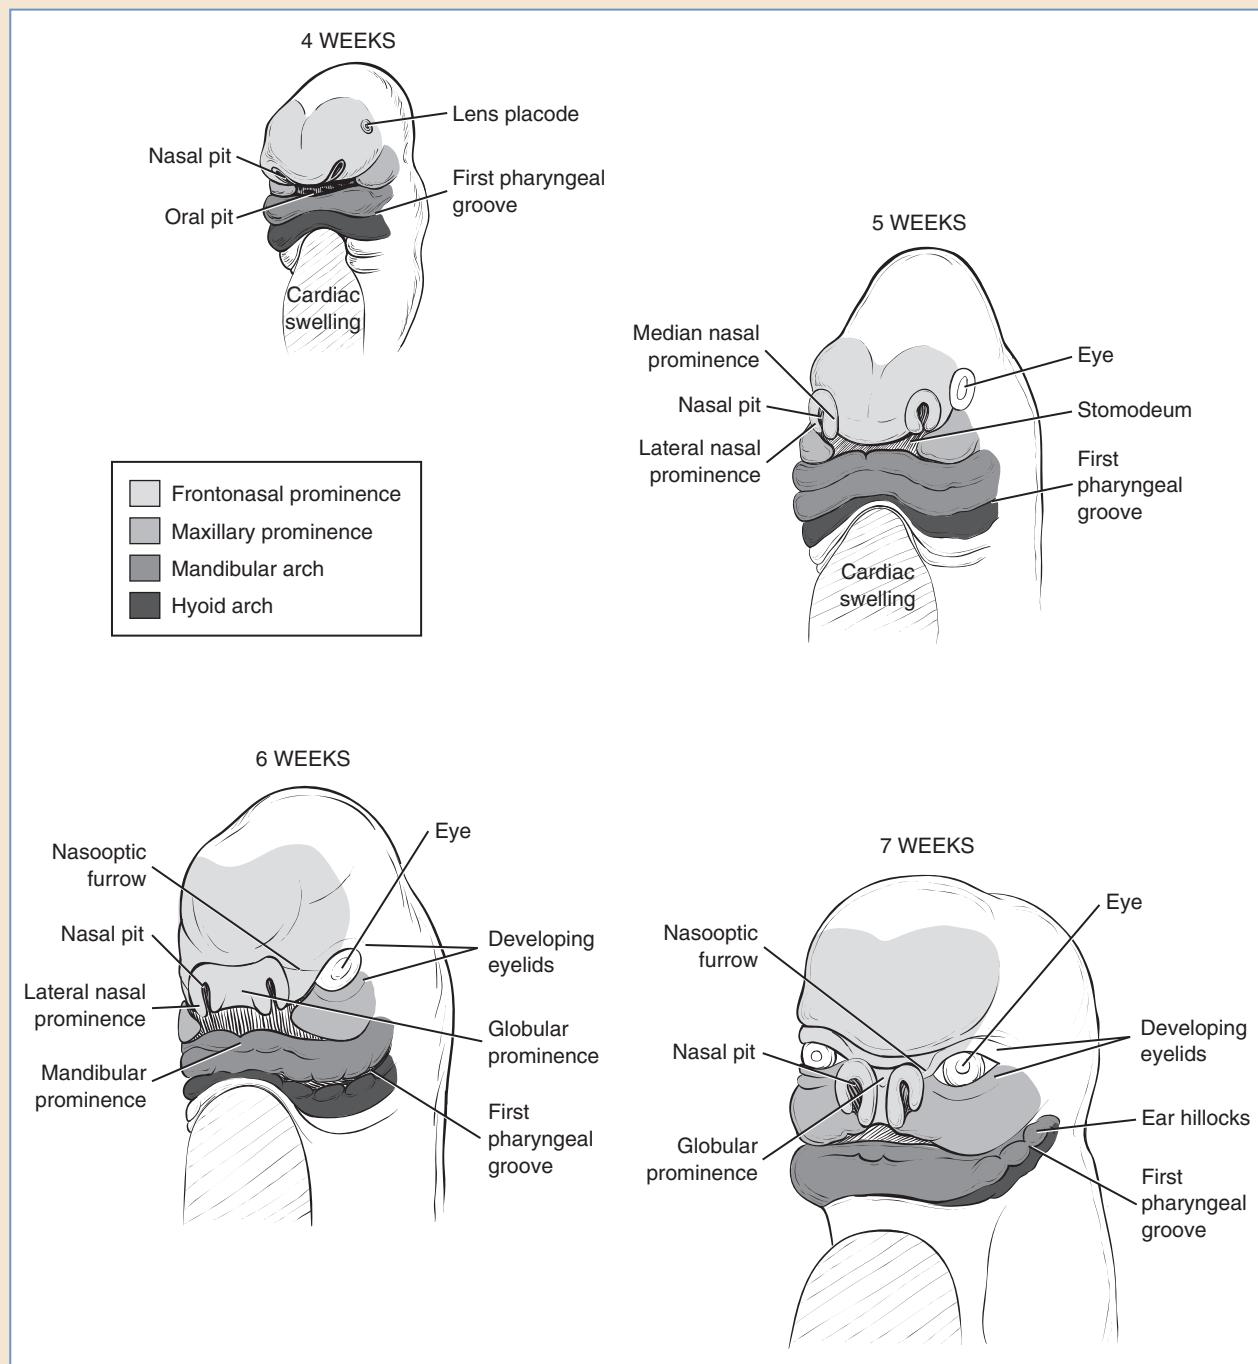

Fig. 22-2 Facial formation from 4 to 7 weeks postconception.

the primary palate. The intermaxillary segment of the upper jaw, the premaxilla, in which the four upper incisor teeth will develop, arises from the medial primary palate.⁹ The rare absence of the primary palate is demonstrated in *premaxillary agenesis*, producing a median cleft lip and palate (CL/P)—a manifestation of holoprosencephaly.¹⁰

Normally four tooth buds, which produce the upper incisor teeth, arise in the primary palate. The location of these four teeth, which are demarcated by incisive fissures in the fetus, usually defines the limits of the primary palate. The canine teeth normally arise in the secondary palate. Most commonly, clefting between the primary and secondary palates occurs at the incisive fissure that separates the lateral incisor and canine teeth.

The *secondary palate*, so called because it forms after the appearance of the primary palate, constitutes both the floor of the nasal cavities and the roof of the mouth. The *secondary palate* is composed of the anterior hard palate and posterior soft palate, and it is an essential component of normal respiration, mastication, deglutition, and speech.

Three elements make up the secondary definitive palate: the two lateral palatal processes projecting into the stomodeum from the maxillary prominences and the primary palate derived anteriorly from the frontonasal prominence. These three elements are initially widely separated as a result of the advancing edges of the palatal processes being deflected down on either side of the protruding tongue, which initially occupies most of the stomodeal chamber.¹¹ Concomitantly, the midline cartilaginous nasal septum descends from the roof of the stomodeum as a feature of nasal capsular development.¹² During postconception week 8, a remarkable transformation of the palatal shelves occurs when they elevate into a horizontal position as a prelude to their fusion with each other, the primary palate, and the nasal septum, thereby partitioning the oronasal chamber.

The transition from vertical to horizontal is completed within hours during postconception week 8. There is a sex difference in the timing of palatal closure; shelf elevation and fusion begin a few days earlier in male embryos than in female embryos¹³; the slight delay possibly accounts for the higher incidence of cleft palates in females. Several mechanisms have been proposed for the rapid elevation of the palatal shelves. They include biochemical transformations in the physical consistency of the connective tissue matrix of the shelves; variations in vasculature and blood flow to these structures, resulting in a sudden increase in tissue fluid turgor; rapid differential mitotic growth; muscular movements; and an intrinsic shelf force.^{14,15} The intrinsic shelf elevating force is generated chiefly by the synthesis, accumulation, and hydration of hyaluronic acid and glycosaminoglycans within the extracellular matrix of the shelves.¹⁶

The withdrawal of the fetus' face from against the heart prominence by uprighting the head facilitates jaw opening. Mouth-opening reflexes and extrinsic tongue muscle activity have been implicated in the withdrawal of the tongue from between the vertical shelves.¹⁷ Depressed fetal swallowing may delay palatal shelf elevation, precluding their conjunction and leading to clefting. Prenatal ultrasonography revealing aphagia has been correlated with cleft palate formation.¹⁸ The fetus must be in a floating position in the amniotic sac to permit jaw movements; in the event of oligohydramnios, deficient amniotic fluid inhibits mouth opening and tongue withdrawal, thereby precluding palatal shelf elevation and thus accounting for a possible source of clefting.

During palate closure the mandible becomes more prognathic and the vertical dimension of the stomodeal chamber increases, although maxillary width remains stable, allowing shelf contact to occur. Also, forward growth of Meckel's cartilage relocates the tongue more anteriorly, concomitant with head elevation. Mandibular growth retardation causes *retrognathia*, which enforces a high tongue position and prevents the shelves from fusing—a series of developmental malformations that lead ultimately to the Pierre Robin sequence.¹⁹

Ossification of the palate proceeds during postconception week 8 from the spread of bone into the mesenchyme of the fused lateral palatal shelves and from trabeculae appearing in the primary palate as premaxillary centers, all derived from the single primary ossification centers of the maxillas.²⁰⁻²² Posteriorly, the hard palate is ossified by trabeculae spreading from the single primary ossification center of each of the palatine bones.

Ossification does not occur in the most posterior part of the palate, giving rise to the soft palate. Myogenic mesenchymal tissue of the first and fourth pharyngeal arches migrates into this faucial region, supplying the musculature of the soft palate and fauces.²³ The tensor veli palatini is derived from the first pharyngeal arch; the levator palatini and uvular and faucial pillar muscles are derived from the fourth pharyngeal arch, accounting for the innervation by the first arch trigeminal nerve of the tensor veli palatini muscle and by the fourth arch pharyngeal plexus and vagus nerves for all of the other muscles.

Fusion of the three palatal components initially produces a flat, unarched roof to the mouth. The hard palate grows in length, breadth, and height, becoming an arched roof for the mouth. The fetal palate increases in length more rapidly than in width between 7 and 18 weeks after conception, after which the width increases faster than the length.²⁴ At birth the length and the breadth of the hard palate are almost equal. The postnatal increase in palatal length is the result of appositional growth in the maxillary tuberosity region and, to some extent, at the transverse maxillopalatine suture.²⁵

Anomalies of the palate occur as a consequence of disturbances to the developmental processes. Successful fusion of the three embryonic components of the palate involves complicated synchronization of shelf movements with growth and withdrawal of the tongue and growth of the mandible and head. Mistiming of any of these critical events, because of environmental agents or genetic predisposition, results in failure of fusion, leading to clefts of the palate.

FREQUENCY

Cleft palate can occur as an isolated cleft palate or in combination with a cleft lip. The isolated cleft palate is genetically and morphologically different from a CL/P. The former has an incidence of 0.45 to 0.5 in 1000 births and is equal across all ethnic backgrounds. On the other hand, the incidence of cleft lip with cleft palate by race is 2.1 in 1000 in Asians, 1 in 1000 in whites, and 0.41 in 1000 in blacks. A large surveillance data-based study recently published²⁶ showed a significant trend toward an increasing prevalence of cleft palate in the United States alone. These data, however, remain under debate, because there is no uniform registration of clefts worldwide. The foremost type of clefting is a *bifid uvula*, which occurs in 2% of the population. The second most frequent type is a *left unilateral complete cleft of the palate and prepalatal structures*. Midline clefts of the soft palate and parts of the hard palate are also common. Complete clefts of the secondary palate are twice as common in females as in males, whereas the reverse is true of velar clefts. Isolated cleft palate generally has a much higher incidence of associated anomalies, resulting in diagnosis of a syndrome in almost one third to one half of patients.²⁷ This is distinctly different from CL/P, in which it is unusual to have other associated anomalies or an identifiable syndrome.

Recurrence risks for cleft palate deformities do not correspond to any Mendelian pattern of inheritance, and it appears that clefting is inherited heterogeneously. This observation is supported by evidence from studies of twins that indicate the relative roles of genetic and nongenetic influences of cleft development. For isolated cleft palate and combined CL/P, if the proband has no other affected first-degree or second-degree relatives, the empiric risk of a sibling being born

with a similar malformation is 3% to 5%. However, if a proband with a combined CL/P has other affected first-degree relatives, the risk for siblings or subsequent offspring is 10% to 20%.

CAUSE

Nonsyndromic clefting of the CL/P in humans has a highly complex etiology, with both multiple genetic loci and exposure to teratogens influencing individual susceptibility.²⁸ The familial clustering of CL/P has been extensively characterized, and epidemiologic studies have proposed monogenic models (putative major locus associated with reduced penetrance),²⁹ multifactorial threshold models, and mixed major gene/multifactorial models to explain its inheritance.²⁹⁻³¹ Clefting can result from a single gene defect either as part of a syndrome (for example, Van der Woude syndrome, Treacher Collins syndrome, velocardiofacial syndrome, Apert syndrome, and other fibroblast growth factor receptor 2 [FGFR2]-mediated craniosynostosis syndromes³²) or as an isolated phenotypic effect (for example, X-linked cleft palate and nonsyndromic, autosomal dominant orofacial clefting). Several studies have suggested that chromosome 6p is a candidate region for a locus involved in orofacial clefting,³³ and linkage studies suggest another susceptibility locus on the long arm of chromosome 4.³⁴ Although evidence of the involvement of a major gene as the cause of CL/P has been reported, orofacial clefting is genetically complex, with no single gene responsible for all forms. Molecular studies provide further insight into the genetic mechanism underlying CL/P, and these findings have important implications with regard to the feasibility of detecting linkage to loci, conferring susceptibility to CL/P.³⁵

Genetic analysis and tissue-specific expression studies support a role for transforming growth factor alpha (TGF- α) in craniofacial development. Numerous studies have confirmed an association at the TGF- α locus with nonsyndromic CL/P in humans,^{30,36} extending the role of TGF- α in craniofacial morphogenesis and supporting an interrelated mechanism for this major gene as the cause of nonsyndromic forms of CL/P.³⁷ In addition, a gene-environment interaction between maternal smoking, TGF- α , and clefting was reported. Shaw et al³⁸ offered evidence that the risk for orofacial clefting in infants may be influenced by maternal smoke exposure alone and in combination (gene-environment interaction) with the presence of the uncommon TGF- α allele. This was supported in a study by Hwang et al,³⁹ in which infants with isolated birth defects (CL/P and control subjects with noncleft birth defects) were tested for an association among maternal exposures, genetic markers, and oral clefts. A modest increase in the less common C2 allele of the TGF- α locus was seen among infants with cleft palate only compared with control subjects with other birth defects, and the association appeared to reflect an underlying interaction between maternal smoking and infant genotype. This apparent gene-environment interaction was also found in those reporting no family history of any birth defects.

Even though the first association studies of CL/P with candidate genes found an association with TGF- α , other candidate genes have also been identified. An association of CL/P with the retinoic acid receptor alpha locus has been reported,³⁵ as well as associations with the *BCL-2 oncogene*, *BCL-3*,⁴⁰ *Sonic hedgehog*, *paired box gene 9* (PAX9),⁴¹ epidermal growth factor receptor,⁴² and several of the known homeobox genes.⁴³ Although some studies suggest that the familial aggregation of nonsyndromic CL/P is likely attributable to the effect of several susceptibility loci acting in a multiplicative fashion,³⁵ others report no interaction between the TGF- α and retinoic acid receptor alpha polymorphisms, even though jointly they appear to account for almost half of the attributable risk of clefting.⁴³

Another gene identified as having a potential role in clefting is transforming growth factor beta 3 (TGF-beta 3). Kaartinen et al,⁴⁴ using TGF-beta 3 null mutant mice, showed an essential function for this gene in normal morphogenesis of the palate, directly implicating a role for this gene in the epithelial-mesenchymal transformation necessary for palatal fusion. Mice lacking TGF-beta 3 had an incompletely penetrant failure of the palatal shelves to fuse, thus leading to cleft palate. In addition to the identification of major genes involved in the cause of nonsyndromic CL/P, information through the human genome project and the use of animal models have facilitated the study of gene environment interactions with respect to orofacial clefting. For example, an interaction has been shown between maternal periconceptual health and the TGF-alpha polymorphism, leading to an increased risk for CL/P.³⁸ In addition, it has been reported that maternal multivitamin supplementation may lead to a reduced risk of CL/P in infants having the TGF-alpha mutation.⁴⁵ Pharmaceutical compounds, such as anticonvulsant drugs,⁴⁶ corticosteroids,⁴⁷ folate antagonists, and retinoids,⁴⁸ as well as alcohol, maternal hyperthermia, and organic solvents/agricultural chemicals, have been shown to cause CL/P in exposed offspring (see following section). However, the mechanism by which many of these compounds exert their teratogenic effect remains unknown. Recent technologic advances, however, will allow the analysis of critical changes in gene expression subsequent to teratogen exposure and will promote the discovery of genetic polymorphisms that will enhance our ability to identify individuals at risk.

Environmental Risk Factors and Oral Clefts

Although the literature regarding the cause of oral clefts is extensive, unique causal factors remain unknown. The widely held belief is that oral clefts are of multifactorial origin, with both genetic predisposition and environmental influence playing a role. The term *environmental* is used in its broadest sense to include characteristics of the individual, such as age, sex, and race, parental behaviors such as smoking and alcohol use, and other types of exposures such as occupational or environmental. Although no strong risk factors for oral clefts have been identified, several potential environmental risk factors have been investigated. Box 22-1 summarizes the major environmental risk factors associated with oral clefts. The association is weak for most risk factors and inconclusive for others.⁴⁹ Most associations are stronger for CL/P rather than for isolated cleft palate.

Box 22-1 Environmental Risk Factors Associated With Oral Clefts

CLASSIFICATION OF DEFECT

It is important to accurately analyze and report a cleft lip and/or palate deformity in a standardized manner. This enables optimal analysis and perioperative planning, and it facilitates multi-center reporting and analysis both retrospectively and prospectively. A classification system presented by the American Association for Cleft Palate Rehabilitation was originally published in 1962, and it was later accepted by the Cleft Palate Association. However, because of its complexity, it was not uniformly accepted. In 1971 Kernahan introduced a simpler classification scheme that may be reported on a diagrammatic Y-shaped symbol, with the incisive foramen represented at the focal point⁹² (Fig. 22-3). This was subsequently used by Millard, and other versions were later proposed to allow easier computerized entry for all anatomic cleft variants.⁹²

PERTINENT NORMAL AND ABNORMAL ANATOMY

The bony portion of the palate is a symmetrical structure with division based on the embryonic origin into the primary and secondary palate. The premaxilla, alveolus, and lip, which are anterior to the incisive foramen, are parts of the primary palate. Structures posterior to it, which include the paired maxilla, palatine bones, and pterygoid plates, are part of the secondary palate. The severity of the clefting of the bony palate varies from simple notching of the hard palate to clefting of the alveolus.

The palatine bone is located posterior to the maxilla and pterygoid lamina. It is composed of horizontal and pyramidal processes. The horizontal processes contribute to the posterior aspect of the hard palate and become the floor of the choana. The pyramidal processes extend vertically to contribute to the floor of the orbit.⁹³

Fig. 22-4 Muscular attachments to the palate.

Fig. 22-5 The effect of the contracting arms of two levator palatini muscles.

Even though the bony defect is important in the surgical treatment of cleft palate, the pathology in the muscles and soft tissues has the greatest impact on the functional result. Six muscles are attached to the palate: the levator veli palatini, superior pharyngeal constrictor, musculus uvulae, palatopharyngeus, palatoglossus, and tensor veli palatini (Fig. 22-4). The three muscles that appear to have the greatest contribution to velopharyngeal function are the levator veli palatini, musculus uvulae, and superior pharyngeal constrictor. The musculus uvulae muscle acts by increasing the bulk of the velum during muscular contraction.^{94,95} The levator veli palatine pulls the velum superiorly and posteriorly to oppose the velum against the posterior pharyngeal wall (Fig. 22-5). The medial movement of the pharyngeal wall, attributed to the superior pharyngeal constrictor, aids in the opposition of the velum against the posterior pharyngeal wall to form the competent sphincter. The palatopharyngeus displaces the palate downward and medially.

Fig. 22-6 The function of the tensor veli palatini is to improve the ventilation and drainage of the auditory tubes.

The *palatoglossus* is mainly a palatal depressor that plays a role in the production of phonemes with nasal coupling by allowing controlled airflow into the nasal chamber. The tensor veli palatini does not contribute to the movement of the velum. The tendons of the tensor veli palatini hook around the hamulus of the pterygoid plates, and the aponeurosis of the muscle inserts along the posterior border of the hard palate. The muscle originates partially on the cartilaginous border of the auditory tubes. The function of the tensor *veli palatini*, similar to the *tensor tympani*, with which it shares similar innervation, is to improve the ventilation and drainage of the auditory tubes (Fig. 22-6).

In cleft palate, the aponeurosis of the tensor veli palatini, instead of attaching along the posterior border of the hard palate, is attached along the bony cleft edges. All the muscles that attach to the palate insert onto the aponeurosis of this muscle. Thus the overall length of the palate is shortened. The abnormality in the tensor veli palatini increases the incidence of middle ear effusion and infection.

The muscle sling of the levator veli palatini is also interrupted by cleft palate. The levator does not form a complete sling. The medial portion of each side attaches to the medial edge of the hard palate. Thus in patients with cleft palate, the effectiveness of the velar pull against the posterior pharyngeal wall is impaired. Of the six muscles, the prevailing theory considers the contribution of the levator veli palatini to be the most important factor in establishing velopharyngeal competence.⁹⁶

PATHOPHYSIOLOGY

The pathologic sequelae of cleft palate include feeding and nutritional difficulties, recurrent ear infections, hearing loss, abnormal speech development, and facial growth distortion. The abnormal communication between the oral and nasal chamber impairs the normal sucking and swallowing mechanism of the cleft infant. Food particles often reflux into the nasal chamber. The abnormal insertion of the tensor veli palatini prevents satisfactory emptying of the middle ear. Recurrent ear infections have been implicated in the hearing loss of patients with cleft palate, and hearing loss may worsen the speech pathology in these patients.

Evidence that repair of the cleft palate decreases the incidence of middle ear effusions is inconsistent; however, these problems are overshadowed by the magnitude of speech and facial growth problems. Speech abnormalities are intrinsic to the anatomic derangement of cleft palate. The facial growth distortion appears to be, to a great extent, because of surgical interventions. An intact velopharyngeal mechanism is essential for the production of nonnasal sounds, and it is a modulator of the airflow in the production of other phonemes that require nasal coupling.⁹⁷ The complex and delicate anatomic manipulation of the velopharyngeal mechanism, if not successfully learned during early speech development, can permanently impair normal speech acquisition.⁹⁸

The closure of the velopharyngeal sphincter prevents the flow of air into the nasal chamber during the production of specific phonemes. This mechanism is essential in the production of nonnasal sounds. Speech impairments specific to velopharyngeal dysfunction include sibilant consonants: the sounds *s*, *z*, *sh*, *zh*, and *ch*; *j* or soft *g* and the intraoral pressure consonants *p*, *b*, *t*, *d*, *k*, and hard *g*. The brain responds to the inability to close the velopharynx by adopting compensatory articulation patterns, which unfortunately are maladaptive and can make speech completely unintelligible. Speech therapy is usually indicated for children with CL/P, generally beginning in the first 2 years and continuing until normal articulation is established.

Multiple studies have demonstrated that the cleft palate maxilla has some intrinsic deficiency of growth potential. The degree of intrinsic growth potential deficiency varies from isolated cleft of the palate to complete CL/P. Growth potential is further impaired by surgical repair. Any surgical intervention performed before the completion of full facial growth can have significant deleterious effects on maxillary growth. Disagreement exists regarding the appropriate timing of surgery to minimize the harmful effects on facial growth and what type of surgical intervention is most responsible for growth impairment. The formation of scar and scar contracture in the areas of denuded palatal bones is most frequently blamed for restriction of maxillary expansion.

The growth disturbance is exhibited most prominently in the prognathic appearance during the second decade of life despite the normal appearance in early childhood. The discrepant occlusal relationship between the maxilla and mandible is usually not amenable to nonsurgical correction.

THE HISTORY OF CLEFT PALATE SURGERY

Rogers expertly reviewed the evolution of cleft palate surgery.^{99,100} The first record of a palatal operation dates back to 500 AD, and it was prompted by inflammation of the uvula. In 1552, Houlier proposed suturing palatal clefts,¹⁰⁰ and 12 years later Ambroise Paré¹⁰¹ illustrated obturators for palatal perforation. In 1764, Le Monnier, a French dentist, successfully repaired a cleft velum with a few sutures and hot cautery of the edges.¹⁰² Von Graefe, 50 years later, produced inflammation of the velar margins before bringing them together in his palate suture, and he is credited with performing the first velar repair of a cleft in 1816.¹⁰³ J.C. Warren¹⁰⁴ performed the first velar closure in America in 1824.

In 1828, Dieffenbach¹⁰⁵ enhanced the surgical treatment of cleft palate by introducing hard palatal mucosa elevation to allow closure of the hard palatal cleft; in 1861 von Langenbeck¹⁰⁶ proposed the creation of a bipediced mucoperiosteal flap that could be mobilized medially to close the palatal cleft. The improved vascular supply to the mucoperiosteal flap significantly decreased the incidence of dehiscence.

The ability to successfully close the palate led to concern about palatal function. It was evident by this time that the short and immobile palate impaired the speech capability of patients with cleft palate. Veau,¹⁰⁷ Kilner,¹⁰⁸ and Wardill¹⁰⁹ described a repair that uses four flaps to accomplish the palatal closure. Two anterior palatal flaps close off the region of the incisive foramen while the posterior palatal flaps are pushed back to lengthen the palate.¹¹⁰

Schweckendiek¹¹¹ advocated the use of a two-stage cleft palate closure. The soft palate was closed early, with closure of the hard palate delayed until several years later. The rationale for the two-stage procedure was to provide improved velopharyngeal function during initial speech development and to accomplish the closure of the hard palate after the cleft narrows with facial growth. Anatomic muscle realignment has also been postulated as essential in improving postoperative velopharyngeal function. These historic developments underlie the existing controversies in management of cleft palate.

Modern Era of Palate Repair

In the late 1950s Randall¹¹² refined the technique originally described by Veau, Wardill, and Kilner. Later, Bardach et al¹¹³ introduced the concept of two-flap palatoplasty, which further improved mobility for coverage of the anterior cleft. Then, in 1986, Furlow¹¹⁴ described his double-opposing Z-plasty technique for palatal repair, which will be described in this chapter.

PLANNING AND TIMING OF PALATAL CLOSURE

The goal of cleft palate treatment is to separate the oral and nasal cavities. Although it is not absolutely necessary for feeding, it is advantageous to normalize feeding and decrease regurgitation and nasal irritation. More important than repairing the oral and nasal mucosa is the repositioning of the soft palate musculature to anatomically re-create the palate so that normal speech can be established. Another goal of palate repair is to minimize restriction of growth of the maxilla in both sagittal and transverse dimensions.

The goals of palatal repair include normal speech, normal palatal and facial growth, and normal dental occlusion.¹¹⁵⁻¹¹⁷ Physicians believe that early palatal repair is associated with better speech results, but early repair also tends to produce more severe dentofacial deformities.¹¹⁸⁻¹²⁰ Randall et al,¹²¹ as well as Lehman and colleagues,¹²² consistently reported that children whose palates were repaired at an earlier age appeared to have better speech and needed fewer secondary pharyngoplasties than those whose surgeries had been delayed beyond the first 12 months.

Noordhoff and associates¹²³ found that children undergoing delayed palatoplasty for cleft palate had significantly poorer articulation skills before the hard palate closure than children of the same age who did not have clefts. These benefits of early cleft palate repair from the standpoint of speech and hearing must be weighed against the increased technical difficulty of the procedure at a younger age and possible adverse effects on maxillary growth.

In our institutions, palatoplasty is performed when the patient is 6 to 12 months of age, depending on the extent of the cleft. Incomplete clefts can be repaired earlier than complete clefts. Surgery at this age results in improved speech development. This protocol is supported by the fact that numerous studies failed to demonstrate an observable difference in underdevelopment of the palatal arch among children undergoing operations at various ages. The surgical intervention

appears to interfere with midfacial growth regardless of the age of the patient at the time surgery is performed.¹²⁴ Patients with Pierre Robin sequence and those with idiopathic micrognathia typically undergo repair at 12 to 13 months of age unless the airway is severely compromised. Some plastic surgeons (Parri and others¹²⁵) advocate early soft palate repair at 3 to 6 months and repair of the remaining cleft by 1 year, although this is not our approach.

SURGICAL TECHNIQUE

Numerous techniques exist for surgical repair of the cleft palate. In general, operations are designed to achieve two primary goals: restoration of hard palate continuity and reconstruction of normal soft palate anatomy and function. The flaps most commonly used for hard palate continuity are bipedicle mucoperiosteal flaps, such as in the von Langenbeck repair, or axial mucoperiosteal flaps based on a single pedicle of the greater palatine vessels, as proposed in the Veau-Wardill-Kilner “pushback” and the Salzer-Bardach two-flap repair.¹²⁶ Vomer flaps may be required to assist in closure of the nasal lining in wide and bilateral clefts. In very wide clefts or in secondary repairs, some authors advocate the use of a calvarial periosteal graft,¹²⁷ buccal myomucosal flap,¹²⁸ acellular dermal matrix,¹²⁹ or free tissue transfer.^{130,131} Another interesting concept in the treatment of wide clefts, which is the focus of ongoing research, is the use of palatal tissue expansion.^{132,133} Black and Gampper¹³⁴ suggested the use of a rotational rather than the traditional advancement mucoperiosteal flap, allowing off-midline closure. However, all the above-mentioned newly developed modalities lack the long-term follow-up necessary for establishing a routine surgical protocol.

Procedures used to re-create the normal anatomy of the soft palate include intravelar veloplasty and the Furlow or double-opposing Z-plasty, in which Z-plasty principles are used to lengthen the palate. Each of these techniques attempts to reconstruct the normal anatomy, including the nasal mucosal layer, the oral layer, and the muscle layer. To reconstruct the muscle sling, the abnormal insertions of the muscles from the back of the hard palate are divided, and the muscles are repositioned to re-create the levator sling across the midline. There is still debate in the literature regarding transaction of the tensor veli palatini tendon. When performed, it allows a more radical reposition and tension-free repair of the levator,^{135,136} although with possible detrimental effects on middle ear ventilation.¹³⁷ Flores et al¹³⁸ suggested tensor tenopexy as an alternative that improves Eustachian tube function and possibly reduces the need for future myringotomies.

Key Elements of Our Approach

Although the basic techniques used in dissection, intravelar muscle repair, and closure of the oral and nasal layers are repeated in each palate repair, the exact design of incisions, both medial and lateral, varies, depending on the anatomy and extent of each case and whether we are addressing a cleft of the primary and secondary palate (unilateral or bilateral) or a cleft of the secondary palate alone. We will discuss the common features, recognizing that the surgeon must vary the approach to fit the needs of the specific case.

The patient is taken into the operating room and a general anesthetic is administered. A Reye tube is used for endotracheal intubation, because it can be positioned out of the field of view for the repair. A prophylactic dose of cefazolin is administered before the procedure. When indicated, pressure equalization tubes are placed before the palate repair.

The patient is positioned at the end of the operating table with his or her head in a soft doughnut cushion. A roll is placed beneath the shoulders. The patient undergoes standard preparation with water-based chlorhexidine suspension and is appropriately draped.

The surgeon inserts a Dingman mouth gag and takes care to preserve the midline position of the endotracheal tube and not overly compress the tongue. The areas of projected incisions are injected with 0.5% lidocaine with 1:200,000 epinephrine. The same solution is then used to hydrodissect the mucoperiosteal flaps from the hard palate. After allowing 10 minutes for hemostasis, the surgeon incises the margins of the cleft. The tip of a No. 12 blade is inserted at the junction of the hard and soft palates and carried posteriorly to the uvula. The incision is then carried

Fig. 22-7 Basic technique of the Salzer-Bardach two-flap repair. **A**, The oral and nasal mucosa are incised and separated from the uvula forward toward the incisive foramen on each side of the cleft. A second incision is completed on each palatal shelf to allow flap elevation. The second set of incisions goes from the anterior extent of the previous incision, continuing posteriorly at the junction of the palatal mucosa and alveolar mucosa. Relaxing incisions are made behind each maxillary tuberosity. **B**, With each full-thickness flap elevated and the greater palatine vessels preserved, the soft palate musculature is taken off its abnormal attachments to the posterior palatine bones. **C**, The nasal mucosa is sutured for a watertight closure from the incisive foramen toward the uvula. The soft palate musculature is sutured across the midline. **D**, The oral mucosa is closed from the uvula forward toward the incisive foramen.

anteriorly along the entire margin of the cleft, leaving a small cuff of nasal mucosa to facilitate nasal lining repair (Fig. 22-7). This incision is carried higher on the oral side of the hard palate in wider clefts to both gain additional nasal lining and have a sturdier border of tissue to suture.

With the oral mucosa placed under tension by a small double-pronged skin hook, the surgeon dissects the muscle from the oral mucosa by repeated gentle strokes with the belly of a No. 15 blade. Care should be taken not to overdissect the muscle from the oral mucosa, because many of the nerve fibers to the levator enter the oral surface of this muscle. The surgeon then moves the skin hook to grab the levator, and with this muscle held under tension, the surgeon dissects the nasal mucosa from the levator by repeated strokes of a No. 15 blade. In our experience, this maneuver facilitates precise and atraumatic dissection of the muscle fibers from the mucosal layers (see Fig. 22-7).

The surgeon makes stab incisions approximately 0.5 cm posterior to the greater tuberosities of the alveolus on either side. Through the stab incision, the surgeon introduces a dental scaler lateral to the hamulus of the pterygoid plates and gently fractures the hamuli on both sides. The incision is brought up from the stab incision toward the greater tuberosity, deviating toward the midline so the attached gingiva is not incised. The surgeon then brings the incision forward all the way to meet with the median incision of the cleft margin in a complete CL/P. For incomplete clefts, the surgeon extends the incision to a point approximately 1 to 2 cm in front of the anterior extent of the cleft (Fig. 22-8).

The dissection of the mucoperiosteal flaps off the hard palate begins from lateral to medial and is then extended posteriorly. The surgeon should identify and carefully preserve the greater palatine vessels that enter the flaps at the back of the hard palate.¹³⁹ With the flap retracted posteriorly, the aberrant insertion of the muscle to the posterior hard palate can be easily visualized and the muscle dissected free. The surgeon should accomplish this liberation both medial and lateral to the vascular pedicle to allow tension-free advancement of the flaps toward the midline. The surgeon dissects the nasal mucosa from the nasal surface of the palatine bones bilaterally with the use of a dental scaler or a gentle muscle hook.

In wide bilateral clefts, a vomer flap can be used to assist in the closure of the nasal layer. After the surgeon injects the vomer liberally with local anesthetic with epinephrine, the flaps should be incised in the midline, elevated bilaterally, and then reflected laterally to allow repair to the cuff of the nasal mucosa.

Careful hemostasis is achieved at this point. It is not unusual to encounter arterial bleeding from small branches of the greater palatine artery at the edges or undersurface of the flaps. This can be stopped with short strokes of bipolar cautery. Oozing from the areas of hamuli fracture is controlled by packing with small pieces of Surgicel gauze. The surgeon should repair the nasal mucosa first. The repair begins anteriorly and proceeds posteriorly to the back of the palate. We use interrupted 5-0 Vicryl sutures on a PS-4C reverse-cutting (hook-shaped) needle, with the knot facing the nasal cavity. The muscle layer is repaired with 5-0 clear nylon simple interrupted sutures with the knot on the nasal side. The surgeon typically places five or six such sutures throughout the length of the muscle from its most anterior border to the uvula. The oral mucosa is repaired with horizontal or vertical mattress 4-0 Vicryl sutures.

The keys to successful closure are well-vascularized flaps and a tension-free closure. Alteration of the position of the initial incisions to provide a sturdier edge of the nasal flap for nasal lining, adequate mobilization of the flaps based on the vascular pedicle only, and the change in the orientation of the flaps from vertical to horizontal are factors that bring the flaps closer together and decrease tension. The mattress sutures on the oral side make for a watertight closure with good surface approximation.

Fig. 22-8 Basic technique of the von Langenbeck cleft palate repair. **A** and **B**, Incisions and initial elevation of full-thickness mucoperiosteal palatal flaps are carried out anteriorly; the muscle dissection separates the oral and nasal mucosa in the soft palate. **C**, The abnormal levator muscle attachments are freed from the posterior hard palate. **D**, The nasal mucosa is repaired from just posterior to the alveolus to the uvula, and levator muscle reconstruction is completed. **E**, The oral mucosa is closed with interrupted sutures from the uvula to the posterior border of the alveolus. Laterally, the palatal flaps are left to heal by secondary intention.

Furrow's Double-Opposing Z-plasty

The double-opposing Z-plasty introduced by Furrow^{114,140} is an important alternative to the extended intravelar veloplasty described previously. We routinely use this technique for the primary repair of submucous cleft palates, and we also recognize its value as a secondary technique to lengthen the palate and correct velopharyngeal dysfunction when preoperative assessment indicates that the previous muscle was inadequate or that palatal lengthening alone may be sufficient to correct velopharyngeal dysfunction. Many centers successfully use this technique with slight modifications for primary palatal repairs.

The surgeon designs opposing Z-plasties on the oral and nasal mucosal surfaces (Fig. 22-9). The posteriorly based flap on each surface is composed of muscle and mucosa, and the anterior surface is composed of mucosa only. In most cases, the limbs of the Z form a 60-degree angle, but in shorter palates the angles are more obtuse. When the lengths of the two sides of the soft

Fig. 22-9 Basic technique of the Furlow double-opposing Z-plasty palate repair. **A**, Location of planned incisions is indicated. **B**, Flaps are elevated. **C**, Nasal side closure is achieved with opposing Z-plasty flaps in the soft palate and nasal flap closure over the hard palate. **D**, Oral side closure of the hard palate and soft palate is completed.

palate are asymmetrical, asymmetrical angles are used. The left-sided limb of the Z is drawn from the position of the hamulus posterolaterally to near the junction of the soft and hard palate anteromedially. The right-sided limb is drawn from a point near the base of the uvula to a point near the hamulus.¹⁴¹

Although claimed unnecessary by Furlow himself, many surgeons use von Langenbeck-type lateral relaxing incisions, deepened into the space of Ernst, and infracture of the hamulus to allow additional medial movement of the palatal shelves. It seems that this extensive lateral release has found its way into the practice of many of the surgeons who use double-opposing Z-plasties for primary cleft palate repair.¹⁴⁰

Despite differences in surgical techniques, a general postoperative routine exists. A tongue stitch of 2-0 silk is placed at the end of the procedure and taped to the child's cheek. This stitch is normally removed the next morning. Hydration is maintained during the immediate postoperative

period with intravenous fluid. Oximetry is continuously monitored for 24 hours. Arm splints are also applied to prevent the child from disrupting the wound by placing fingers or sharp objects in the mouth. Oral feeding may be initiated postoperatively in the evening with a syringe or by having the patient drink from a cup. Nipple feeding is avoided for 10 days. Patients can usually be discharged with arm splints on postoperative day 1.

Treatment of Submucosal Cleft Palate

Submucosal cleft palate is usually characterized by the triad of bifid uvula, a bony notch at the back edge of the hard palate, and a translucent midline zone.¹⁴² In surveys of classic stigmata of submucosal cleft palate among the general population, the incidence has been reported to be 0.02% to 0.08%,¹⁴³ but the true incidence of submucosal cleft palate remains unknown, because many patients remain asymptomatic throughout life. Some patients presented with velopharyngeal inadequacy (VPI) during speech development. Others presented with hearing loss or recurrent ear effusions. The incidence of occult and classic submucosal cleft palate in patients with VPI is 10% to 22% and 17% to 44%, respectively.^{144,145} Many surgical approaches have been described for the treatment of submucosal cleft palate, including a pharyngeal flap, palatal pushback techniques, intravelar veloplasty, or a combination of these. A recent retrospective study by Ha et al¹⁴⁶ found that surgical correction is successful regardless of technique and age, but earlier recognition is advantageous for minimizing speech impairments. We think that the primary surgery for a submucosal cleft palate should be intravelar veloplasty, because the realignment of the velar musculature provides the greatest improvement in speech. This is achieved without the complications of the pharyngeal flap, such as sleep apnea and airway compromise.

Use of Facial Artery Myomucosal Flap for Palate Reconstruction

The *facial artery myomucosal* (FAMM) flap was originally conceptualized by Pribaz et al,¹⁴⁷ who combined the principles of nasolabial and buccal mucosal flaps. The flap has been used successfully in a variety of oronasal mucosal defects. The original series consisted of 15 patients, 4 of whom were patients with congenital cleft palates. The flap is a facial artery–based axial flap, which consists of mucosa, submucosa, a small amount of buccinator muscle, the deep plane of the orbicularis oris muscle, and the facial artery and venous plexus. The anatomic relationship between the facial artery and vein within the pedicle was further refined in a later article.¹⁴⁸ It can be designed either as a superiorly based (retrograde flow) or inferiorly based (anterograde flow) flap. It can also be used as a unilateral or bilateral flap. Relevant indications are oronasal fistula closure or palatal lengthening for VPI. Palatal lengthening with the bilateral FAMM should also be considered as the primary approach to palatal lengthening in patients in whom the palate is congenitally short, where there is no evidence of submucous clefting, or other anatomic anomaly other than shortness. The FAMM in this case allows the addition of tissue without the disruption of the intact musculature and does so as in other patients without a compromised airway (Fig. 22-10).

Surgical Technique: Facial Artery Myomucosal Flap for Palate Reconstruction

The course of the facial artery is outlined intraorally with Doppler ultrasonography. The flap is centered over the artery with an oblique orientation, extending from the retromolar trigone to the level of the ipsilateral gingival labial sulcus at the level of the alar margin (see Fig. 22-10). The width of the flap is 1.5 to 2 cm and is well anterior to Stensen's duct. Dissection starts at the distal end of the flap, with an incision through the mucosa and buccinator muscle. The facial artery is then identified, ligated, and cut. The rest of the flap is then incised, and the dissection proceeds just deep to the facial vessels, taking only a minimum of overlying buccinator muscle and orbicularis muscle near the oral commissure. A long pedicle (up to 8 to 9 cm in adults) can be raised,

Fig. 22-10 **A**, With a probe in Stensen's duct, the 10 to 12 mm wide flap is oriented starting posterior to the maxillary tuberosity and tapered toward the oral commissure. Drawing and elevation facilitated by a traction suture at the oral commissure. **B**, The right-sided myomucosal flap elevated. **C**, The soft palate is released from the posterior hard palate with a full-thickness incision beginning a few millimeters behind the hard palate and extending on either side to the border of each flap. **D** and **E**, The right flap is rotated clockwise, turned over, and inset into the defect with the mucosal surface directed nasally. **F**, The donor site is closed in the right cheek. **G**, The left-sided flap is outlined. **H**, The left-sided myomucosal flap is rotated counterclockwise and inset on top of the right flap. The immediate lengthening effect on the soft palate is shown. **I**, Two years after surgery, the flap is well healed. The increase in length was 1.5 cm.

based either superiorly with a pivot point at the gingival sulcus or inferiorly with the pivot at the retromolar trigone. The donor site is closed, and care is taken to not to damage Stensen's duct. When the procedure is performed to close an oronasal fistula, the edges of the fistula are trimmed first. The FAMM flap is inset into the oral side of the fistula and sutured to the oral mucosa with 5-0 and 4-0 Vicryl sutures. When the procedure is performed for palatal lengthening, a long incision is made through all the layers of the palate at the junction between the hard and soft palates. One of the FAMM flaps is inset to reconstruct the nasal side of the oronasal fistula, whereas the contralateral flap is inset to reconstruct the oral side. The surgeon may find that it is easier to elevate each flap and close the greater part of each donor site, then make the transverse inci-

sion across the palate, and finally inset each flap as an alternative to the sequence shown in Fig. 22-10. In this technique the soft palate can be lengthened and pushed back toward the posterior pharyngeal wall. This approach is similar to the buccopharyngeal flap used by Hens and others,¹⁴⁹ emphasizing the desire to not disturb the nasopharyngeal diameter to preserve airway.

MANAGEMENT OF COMPLICATIONS

Complications related to cleft palate repair are generally infrequent. Complications include bleeding, airway compromise, infection, dehiscence, and fistula formation.¹⁵⁰ Significant bleeding is rare, but it may require a return to the operating room for exploration and hemostasis. In a retrospective analysis of 709 patients, there was a 2.4% rate (17 of 709) of take-back to the operating room in the immediate postoperative period for control of bleeding, although no blood transfusions were required.¹⁵¹ Airway compromise is also rare, but it may be life-threatening when present. Infants with Pierre Robin sequence or other congenital anomalies affecting the airway, either directly or indirectly, are at highest risk for airway problems.¹⁵²

Fistula formation is surgeon dependent and to a lesser extent depends on the technique used and the \rightarrow type of cleft.^{150,153} The incidence of fistula formation has been reported to be between 0% and 34%, with the average between 3% and 4%. Most fistulas are small and are easily repaired during subsequent surgical procedures. Anterior fistulas near the alveolus are not repaired, because they are rarely symptomatic and are usually addressed at the time of bone grafting.^{154,155} Large fistulas or fistulas occurring in scarred, reoperated palates are difficult to repair. It is a common mistake to try repairing these defects with small local flaps—a strategy that almost always results in fistula recurrence, with further scarring of local tissues and subsequent limitation of reconstructive options. The surgeon should always use large flaps to successfully treat these defects. Large mucoperiosteal flaps, tongue flaps, FAMM flaps, and free microvascular tissue transfer should be considered in addressing this difficult reconstructive problem¹⁵⁶; the latter procedure is more commonly used to repair large fistulas after tumor extirpation.

VPI will be discussed in Chapter 23. Nonetheless, it is worth commenting here that the issue of airway compromise is one of the major concerns that is faced in the decision of treatment of nasal air emission (NAE). The approaches range from repeat repair with intravelar veloplasty if not done, Furlow technique if the gap is small and the palate is short, to some type of pharyngoplasty. We think that a greater degree of palatal lengthening can be obtained with the use of the bilateral FAMM (as described previously) or the buccopharyngeal flap. Both techniques add significantly more length than the Furlow Z-plasty and avoid airway compromise.

In a large multicenter study,¹⁵⁷ secondary surgery after isolated palate repair was done in 13.6% of patients by the age of 16 years, with higher rates in complete clefts. The risks of secondary surgery over time showed a bimodal distribution; the first peak within the first postoperative year and the second peak between 3 and 5 years after surgery. The first risk peak after secondary surgery reflects the short-term complications that must be addressed within the first postoperative year. The second peak reflects the longer-term complications diagnosed at the age at which children reach speech milestones.

OUTCOMES

The most important outcomes in cleft palate repair are the establishment of normal speech and hearing.¹⁵⁸ Confirmation of proper muscle repositioning and velar function can be assessed with

MRI and videofluoroscopy imaging, respectively. These issues, however, do not necessarily correlate with speech impairment.¹⁵⁹ The most important step for achieving good outcomes is a well-executed surgical repair by an experienced surgeon. Once palate repair has been performed and pressure equalization tubes have been placed, frequent evaluation by a multidisciplinary cleft team is necessary so that adjunctive measures can be undertaken when speech abnormalities are identified. Many patients with cleft palate have some language delays and articulation errors; therefore early speech intervention is both recommended and beneficial.

Despite a well-executed palatoplasty, careful speech follow-up, and early intervention, about 15% to 20% of patients will develop speech production disorders, most commonly velopharyngeal dysfunction. This percentage seems independent of the type of palatoplasty.¹⁶⁰ Velopharyngeal dysfunction is diagnosed clinically by a constellation of symptoms that include pathologically incurred nasal resonance (hypernasality), misarticulation, escape of air through the nose (nasal emission), and aberrant facial movements (grimacing).¹⁶¹⁻¹⁶³

Successful outcome analysis in cleft surgery is difficult to obtain for a multitude of reasons.¹⁶⁴⁻¹⁶⁹ Much of the cleft literature is descriptive and focuses on anatomic integrity and aesthetic results.^{170,171} More recently, comparative studies have been reported that assess functional outcome with respect to speech,¹⁷² dentoskeletal development,¹⁷³ psychological issues, and airway.¹⁷⁴ Critical information on long-term outcomes in cleft care is hard to come by. The time lapse between surgery and measurement of outcome (at craniofacial growth maturity in mid to late adolescence) creates major difficulties for clinical researchers.^{170,171,175} Retrospective study requires information on primary management practices 5, 10, and 15 years previously and presupposes clearly described treatment protocols. Even when this exists, such practices may have little relevance to the research questions of current interest. Where treatments have been described with insufficient detail, treatment-related variation and outcome may remain undetectable. Similarly, if the results of prospective studies are to be timely and relevant, it is important that they be completed within a reasonable length of time. Unfortunately, the measurements of some aspects of outcome (for example, dentoskeletal development) are best deferred until patients reach maturity.

Comprehensive examination of the outcome of treatment should be multifaceted, especially because trade-offs may occur. For example, delayed closure of the hard palate may reduce growth disturbance but increase speech impairment. Evidence that adequate palatal closure has a salutary effect on the ubiquitous problem of middle ear pathology, the possible benefits of avoiding disuse atrophy in the levator veli palatini musculature, and the early establishment of swallowing and crying indicate that closure may provide many benefits if done much earlier. None of these factors has been clarified by objective studies. Prospective, longitudinal investigations of the clinical management of CL/P are necessary to answer the three central problems of that management: the best time to treat, the techniques of treatment most appropriate in a particular patient, and the effects of treatment.^{163,176} The treating physician must keep in mind all of the goals listed previously to provide an environment that promotes a successful outcome.

CONCLUSION

The management of patients with cleft palate is complex. The functional goals of cleft palate surgery are to facilitate normal speech and hearing without significantly affecting facial growth of the child. To achieve these goals, cleft palate teams must provide multidisciplinary care and monitor the functional outcomes of surgery.

KEY POINTS

- Oral clefts are of multifactorial cause, with both genetic predisposition and environmental influences playing a role.
- Orofacial clefting is genetically complex, with no single gene responsible for all forms.
- Clefting can result from a single gene defect either as part of a syndrome (for example, Van der Woude syndrome, Treacher Collins syndrome, and velocardiofacial syndrome) or as an isolated phenotypic effect (for example, X-linked cleft palate and nonsyndromic, autosomal dominant orofacial clefting).
- Potential environmental risk factors that have been associated with oral clefts include smoking, alcohol, caffeine, benzodiazepines, and corticosteroids.
- With the higher incidence of syndromal association with cleft palate alone, all patients should be evaluated by a geneticist.
- Given the potential association of Stickler syndrome with Pierre Robin sequence, all babies with Pierre Robin sequence should have a screening by a pediatric ophthalmologist.
- It is important to accurately analyze and report a cleft lip and/or palate deformity in a standardized manner. Kernahan's classification scheme (modified by Millard and others) is reported on a diagrammatic Y-shaped symbol, with the incisive foramen represented at the focal point.
- The premaxilla, alveolus, and lip, which are anterior to the incisive foramen, are parts of the primary palate. Structures posterior to it, which include the paired maxilla, palatine bones, and pterygoid plates, are part of the secondary palate.
- The pathologic sequelae of cleft palate include feeding and nutritional difficulties, recurrent ear infections, hearing loss, abnormal speech development, and facial growth distortion.
- The muscle sling of the levator veli palatini is interrupted by cleft palate. In patients with cleft palate, the effectiveness of the velar pull against the posterior pharyngeal wall is impaired, and velopharyngeal incompetence results.
- The abnormality in the tensor veli palatini increases the incidence of middle ear effusion and middle ear infection in children with cleft palate. Early evaluation by a pediatric otolaryngologist is imperative.
- An intact velopharyngeal mechanism is essential for production of nonnasal sounds and is a modulator of airflow in the production of other phonemes that require nasal coupling. Speech impairments specific to velopharyngeal dysfunction include sibilant consonants, the sounds *s*, *z*, *sh*, *zh*, and *ch*; *j* or soft *g*; and the intraoral pressure consonants *p*, *b*, *t*, *d*, and *k* and hard *g*.

- Cleft palate maxilla has some intrinsic deficiency of growth potential. Growth potential is further impaired by surgical repair. The growth disturbance is exhibited most prominently in the prognathic appearance during the second decade of life despite the normal appearance in early childhood.
- Palatoplasty is performed at 6 to 12 months of age, depending on the extent of the cleft. Patients with Pierre Robin sequence and those with idiopathic micrognathia typically undergo repair at 12 to 14 months of age unless the airway is severely compromised.
- In Furlow's palatoplasty, the posteriorly based flap on each surface is composed of muscle and mucosa, and the anterior surface is composed of mucosa only.
- In intravelar veloplasty, the muscle layer is repaired with 5-0 clear nylon simple interrupted sutures with the knot on the nasal side. Five or six such sutures are typically placed throughout the length of the muscle from its most anterior border toward the uvula.
- The FAMM flap is a reliable surgical modality for persistent oronasal fistula after cleft palate repair.
- Submucosal cleft palate, often undiagnosed until speech development, may lead to VPI, chronic middle ear effusion, and hearing loss.

This is an excellent description of the morphogenesis of facial development in the human, describing palate shelf movement and the transition from vertical to horizontal in positioning of the shelves during the eighth week of gestation. There is a sex difference in the timing of palatal closure. Shelf elevation and fusion begin a few days earlier in male embryos than in female embryos; the slight delay possibly accounts for the higher incidence of cleft palates in females.

Although the literature regarding the cause of oral clefts is extensive, unique causal factors remain unknown. In evaluating the role of specific risk factors in epidemiology, several criteria are examined for causality. These include consistency, strength of association, biologic plausibility, temporal sequence, and dose-response relationship. Often there is a remarkable lack of consistency for several of the risk factors discussed here. This study demonstrates that many of the measures of association are not strong. In addition, usually there is little information regarding the temporal dose-response relationship. Therefore making inferences about the causality of oral clefts is a largely inconclusive task.

53. Lief S, Olshan AF, Werler MM, et al. Maternal cigarette smoking during pregnancy and risk of oral clefts in newborns. *Am J Epidemiol* 150:683, 1999.
The results of previous epidemiologic research on the possible association between maternal smoking during pregnancy and the risk of oral clefts in offspring have been inconsistent. This may be partly because of methodologic limitations, including imprecise measurement of tobacco use, failure to consider causal heterogeneity among types of oral clefts, and confounding results. This analysis further evaluated the effect of first-trimester maternal smoking on oral facial cleft risk by examining the dose-response relationship according to specific cleft type and according to whether additional malformations were present. A number of factors, including dietary and supplemental folate intake and family history of clefts, were evaluated as potential confounders and effect modifiers.
54. Wyszynski DF, Beaty TH. Maternal cigarette smoking and oral clefts: a meta-analysis. *Cleft Palate Craniofac J* 34:206, 1997.
A meta-analysis was performed to estimate the association between maternal cigarette smoking and risk of having a child with a nonsyndromic oral cleft. These analyses suggest a small but statistically significant association between maternal cigarette smoking during the first trimester of gestation and increased risk of having a child with a cleft lip with or without cleft palate.

Cleft lip with or without cleft palate (CL \pm P) is the most common congenital malformation reported among infants of epileptic mothers. This study examined the relative roles of anticonvulsant teratogenicity and other factors responsible for this association. Among 175 families with a proband with isolated CL \pm P, there were 13 parents with epilepsy and a high frequency of other family members with CL \pm P and epilepsy. Evaluation of the 13 cases suggested that teratogenicity of anticonvulsant drugs was not the primary factor responsible.

This study sought to determine whether exposure to benzodiazepines during the first trimester of pregnancy increases the risk of major malformations or cleft lip or palate. In the analysis of cohort studies, fetal exposure to benzodiazepine was not associated with major malformations or oral cleft. Analysis of case-control studies showed an association between exposure to benzodiazepines and the development of major malformations or oral cleft alone. Pooled data from cohort studies showed no association between fetal exposure to benzodiazepines and the risk of major malformations or oral cleft. On the basis of pooled data from case-control studies, however, there was a significant increased risk for major malformations or oral cleft alone. Until more research is reported, level 2 ultrasonography should be used to rule out visible forms of cleft lip.

84. Munger RG. Maternal nutrition and oral clefts. In Wyszynski DF, ed. *Cleft Lip and Palate: From Origin to Treatment*. New York: Oxford University Press, 2002.
This study, along with others, demonstrated an increased risk for CL/P with high alcohol intake, with significant point estimates ranging from 2.8 to 4.0. The fact that there was no increased risk demonstrated for cleft palate in all but one study may be explained by inadequate statistical power to detect an increased risk.

87. Erickson JD. Risk factors for birth defects: data from the Atlanta Birth Defects Case-Control Study. *Teratology* 43:41, 1991.
The Atlanta Birth Defects Case-Control Study data contain information obtained from interviews with the parents of 4900 infants born with major birth defects and with the parents of 3000 infants born without defects. Birth defects were classified into 92 groups and cross-tabulated by 105 exposure/risk factor variables; data from selected cross-tabulations are presented. These data can be used to evaluate hypotheses arising from other sources and for the purpose of "generating" hypotheses.

96. Kriens OB. An anatomical approach to veloplasty. *Plast Reconstr Surg* 43:29, 1969.
This paper and the excellent anatomic drawings of normal and cleft palate anatomy formed the basis for the intravelar veloplasty, showing how repair of the palate without levator muscle release left the muscles in an orientation in which the vector of pull was not oriented correctly for optimal velopharyngeal closure. This paper shows how muscle release and intravelar veloplasty place the muscle in a more functional and "normal" position.

114. Furlow LT Jr. Cleft palate repair by double opposing Z-plasty, Plast Reconstr Surg 78:724, 1986.
In an attempt to improve speech results after palate repair while allowing adequate maxillary growth, a palatoplasty with two opposing Z-plasties of the soft palate—one of the oral and one of the nasal layers—was used in 22 infants. The Z-plasties facilitated effective dissection and redirection of the palatal muscles to produce an overlapping muscle sling and lengthen the velum without using tissue from the hard palate, which permits hard palate closure without pushback or lateral relaxing incisions.

Circular Closure Pattern of the Velopharyngeal Mechanism; Coronal Closure Pattern of the Velopharyngeal Mechanism; Submucous Cleft Palate With Sphincter Closure Pattern of the Velopharyngeal Mechanism.

Velopharyngeal dysfunction (VPD) is a distinct malfunction of the velum and pharyngeal musculature that can cause a collection of speech and swallowing disorders. The causes can be multifactorial, but the fundamental problem is anomalous velopharyngeal closure that prevents normal speech production. The reasons for this may be anatomic, neurologic, behavioral, or a combination of these. Some have structural abnormality (such as a cleft palate) and others have a neurologic problem (for example, myasthenia gravis). In this chapter we will focus on the structural abnormalities. Most patients who have untreated VPD will develop compensatory maladaptive articulations in an effort to be understood by others. Patients often present with hypernasality, nasal emissions, or facial grimacing during speech. Failure of the sphincteric mechanism is frequently the result of a structural defect of the pharyngeal walls or soft palate at the level of the nasopharynx.

This chapter discusses the causes of VPD, the approach to diagnosis and management, and surgical approaches for optimizing velopharyngeal sphincter function while preventing airway morbidity.

ANATOMY

Velopharyngeal Mechanism

Within the region of the velopharynx, multiple muscles work together in normal circumstances to close what is called the *velopharyngeal sphincter*. The two anatomic structures involved are the velum, or soft palate, and the pharynx, including the lateral and posterior pharyngeal walls. When functioning in concert, the muscles of these structures close off the nasopharynx, a critical movement for normal speech production and swallowing. The principle muscles that constitute the velopharyngeal sphincter include the levator veli palatini, the palatopharyngeus, and the superior pharyngeal constrictor. Lesser contributions come from the tensor veli palatini, the palatoglossus, the musculus uvulae, and the salpingopharyngeus¹ (Fig. 23-1).

The tensor veli palatini is innervated by cranial nerve V (trigeminal nerve); the rest of the muscles are innervated by contributions from cranial nerve IX (glossopharyngeal nerve) and cranial nerve X (vagus nerve) where they form the pharyngeal plexus.

Fig. 23-1 Velopharyngeal anatomy.

Closure Patterns

The composite movements of the lateral and posterior pharyngeal walls and the velum close the velopharyngeal port in deglutition and during oral speech sounds. These movements open the port for breathing and some nasalized articulations. Despite the variance in how the velopharyngeal mechanism achieves closure, characteristic patterns of movement have been observed using direct visualization with nasopharyngoscopy. These typical patterns of closure include coronal, sagittal, circular \pm the Passavant ridge, and bow-tie-type closure¹ (Fig. 23-2, *A* through *E*).

Continued

ETIOLOGIC FACTORS

In this chapter we will discuss the concept of VPD that is present as speech develops. In a study of 148 patients, some causes of secondary VPD have been established² (Fig. 23-3). This is distinguished from speech problems resulting from primary cleft palates in that it has numerous causes, not all related to cleft palate (Box 23-1). For information on cleft palate, please refer to Chapter 22.

Secondary Cleft Palate Dysfunction

The normal anatomy of the velopharyngeal mechanism is altered in cases of cleft palate. In addition to the concomitant disruption of the mechanism by the cleft space, muscular function is altered, especially that of the levator veli palatini, a major contributor to velar excursion during speech. During proper primary repair of the cleft palate, the levator muscles should be liberated from the abnormal insertion on the hard palate.

Box 23-1 Common Causes of Velopharyngeal Dysfunction

- Secondary cleft palate dysfunction
- Submucous cleft palate
- Velocardiofacial syndrome (22q)
- Tonsillectomy
- Midface advancement

A subset of patients presents after cleft palate repair with VPD. Whether from improper surgical technique or uncontrolled contracture, these patients have a scarred, immobile, and often short soft palate, inadequate to maintain appropriate closure of the velopharynx. A post-operative oronasal fistula may also cause VPD. Its presence and contribution to hypernasality are established and considered in the overall treatment plan. However, these fistulas do not contribute to VPD.

Submucous Cleft Palate

Submucous clefts can be difficult to identify. They occur where mucosal continuity over a levator muscle is discontinuous and oriented as it would be in a cleft palate. Calnan described a triad of findings in submucous cleft palates, including the zona pellucida, a bifid uvula, and a palpable notch at the posterior hard palate. Speech findings in patients with submucous cleft palate can run the gamut from normal or near-normal to grossly abnormal^{3,4} (Fig. 23-4).

Fig. 23-4 Submucous cleft palate. (Courtesy of Robert J. Shprintzen, PhD, President, The Virtual Center for Velo-Cardio-Facial Syndrome, Inc.)

Velocardiofacial Syndrome (22q11.2)

22q11.2 deletion syndrome is known by many names, including *DiGeorge syndrome*, *velocardiofacial syndrome* (VCF), *Shprintzen syndrome*, and *CATCH22*, among others. The abundance of names is a side effect of the variability of the syndrome. It affects approximately 1 in 4000 people. Inheritance is considered autosomal dominant; however, most cases are not inherited. Del 22q has many possible signs and symptoms that can vary widely, even among people affected within the same family. The findings in del 22q commonly include conotruncal cardiac malformations at a rate as high as 74%. Palatal abnormalities may be present in up to 69% of patients and include VPD, submucous cleft palate, bifid uvula, and cleft palate. A host of other associated abnormalities can occur that are beyond the scope of this text.^{5,6}

Bezuhly et al⁷ reported that their series of 23 patients with 22q and submucous cleft palates repaired with Furlow Z-plasty or pharyngeal flaps had similar results between groups. In the 22q group, they noted the need for more revisions and an increased median time to normal resonance by a factor of 5. In their study, these patients were 3.6 times less likely to achieve normal resonance.

Anomalous internal carotid arteries have been shown to be a frequent feature of velocardiofacial syndrome. These vessels pose a potential risk for iatrogenic injury and hemorrhage during velopharyngeal narrowing procedures. Iatrogenic injuries to the carotid artery during velopharyngeal surgery are strikingly absent in the literature. Occasionally, transmission of vascular pulsations through floppy, redundant mucosa may be mistaken as an ominous vessel. Careful preoperative evaluation and dissection will frequently obviate the need for imaging studies. Our center does not order routine angiography of these patients before speech surgery. Baek et al⁸ showed that such imaging is not cost effective (Fig. 23-5).

Tonsillectomy

Although not common, a tonsillectomy and an adenoidectomy may lead to VPD. There are case reports of cranial nerve injuries in the vicinity of the operative field leading to postoperative VPD. Additionally, removal of bulk from the pharynx may contribute mechanically to VPD, preventing complete closure presumably from the prior adaptation of the existing musculature to the

Fig. 23-5 MRI showing a medially displaced right internal carotid artery (*Rt. ICA*). (*A*, Artery; *Lt. ICA*, left internal carotid artery; *V*, vein.)

large, space-occupying tonsils and adenoids. A number of posttonsillectomy patients with VPD had an undiagnosed submucous cleft palate. Other identified causes of VPD in posttonsillectomy patients are neuromuscular disorders, poor palate mobility, behavioral disorder, postoperative nasopharyngitis, and scarring.⁹

Midface Advancement

Midface advancement with LeFort-level osteotomies is a common procedure for managing malocclusion and/or orbitomalar correction in cases of orofacial clefting and craniofacial syndromes. There are several predictors for the development of VPD. A short palate and a deep pharynx on cephalometric evaluation has been associated with postoperative VPD after a LeFort I-level osteotomy in cleft patients.¹⁰ Another clear predictor of VPD after midface advancement is the total distance of advancement. Longer distances are associated with a deeper pharynx and a higher chance for VPD. Finally, patients with preoperative VPD are more likely to have increased VPD after a midface advancement. Initially after midface correction, VPD may be present. A formal evaluation of speech should not begin until approximately 6 months after these procedures, because VP adaptation can occur, lessening the need for a formal evaluation and surgical treatment. In cleft patients with severe maxillary hypoplasia, midface distraction osteogenesis has been shown to have improved results over traditional orthognathic surgery, especially for distances of more than 10 mm.^{11,12}

EVALUATION

Coordination of Care

Patients with VPD should be managed by an interdisciplinary team. Critical members of the team addressing speech should include a craniofacial surgeon, a skilled speech-language pathologist (SLP), and a geneticist. A team approach is essential for customized treatment planning and better outcomes.¹³

Patient History and Physical Examination

When taking a history and performing a physical examination for patients presenting with VPD, surgeons should first focus on determining the underlying cause. (These were discussed previously.) Each of these is approached as a unique problem. In general, team members determine whether a patient's speech is intelligible and whether it has caused psychosocial problems or frustration, because others, including parents, siblings, peers, and teachers have difficulty understanding it.

During a physical examination, the size of the adenoid pad and the tonsils and the presence of fistulas are noted. A palpable palatal notch at the junction of the soft and hard palate, a zona pellucida along the soft palate, and a bifid uvula may be clues that a patient has a submucous cleft palate.

Another important detail to note is a history of obstructive sleep apnea (OSA). If this a concern preoperatively, then polysomnography may be indicated before speech surgery, because the condition can worsen.

Speech Assessment

The hypernasality caused by VPD results from abnormal resonance in the vocal tract or abnormal airflow. The symptoms of VPD are auditory-perceptual; therefore the standard for assessment is a trained listener's judgment. Most SLPs associated with a cleft palate team report that they rely primarily on listener's judgment of resonance and articulation in evaluating velopharyngeal function.¹⁴ This is a specialty area in speech pathology, and not all SLPs have the skills to judge the characteristics associated with VPD.¹⁵ The role of SLPs is to help determine whether a patient has VPD and whether it is caused by structure, neuromotor deficits, or abnormal speech learning.

Perceptual Testing

An SLP will complete formalized articulation testing and will have the patient engage in syllable repetition and sentence repetition. A spontaneous connected speech sample is obtained. Therapists use appropriate speech samples to obtain the information needed for a definitive diagnosis.¹⁶ Speech samples need to be developmentally appropriate but also contain the appropriate types of phonemes.

Sentence repetition is a good way to evaluate articulation and velopharyngeal function. Using a battery of sentences such as those in Table 23-1, clinicians can quickly assess articulation, nasal emission, and resonance in a connected speech activity.¹⁶ This is a quicker and more valid assessment of normal speech production than a single-word, formal articulation test.^{16,17} Articulation and resonance are assessed during connected speech, which increases the demands on the velopharyngeal valving system to maintain closure. Hypernasality and nasal air emission are more apparent in connected speech than in single words or sentences. An increase in articulation errors is common during the production of longer, spontaneous utterances.¹⁵

Table 23-1 Sample Sentences for Assessment of Articulation and Resonance

p	Papa plays with a puppy.	f	I have five fingers.
b	Buy baby a bib.	v	He visits the cave.
m	Mama makes lemonade.	l	I like yellow lollipops.
w	Wade likes the water.	s	Sissy sees the sky.
y	You have a yellow yo-yo.	z	Zip up the zipper.
h	He has a big horse.	sh	She goes to the shop.
t	Take Teddy a toy.	ch	Chad rides the choo choo.
d	Daddy does dishes.	j	John told a joke to Jim.
n	Nancy is not here.	r	Ross had a red fire truck.
k	I like cookies and crackers.	er	The teacher is a doctor.
g	Go get the wagon.	th	That's my toothbrush.
ng	Put the ring on the finger.	blends	Splash, sprinkle, street

Visual Detection

A mirror examination helps to determine whether nasal air escapes while a patient produces oral sounds. A mirror is held under the nares during the production of pressure sensitive sounds. Nasal air emission is noted as condensation (fogging of the mirror). Consistent fogging on the mirror across all sound productions suggests decreased velopharyngeal closure from structure or neuromotor causes. Inconsistent fogging on the mirror can indicate abnormal speech learning, especially if it is isolated to one sound class (for example, sibilants).

Nasal grimacing is another visual indication of nasal air escape. It presents as a contraction near the nasal bridge and/or on the side of the nose. It occurs as an overflow muscular response to excessive effort in producing velopharyngeal closure.¹⁶

Instrumental Assessment

An experienced SLP can assess velopharyngeal function during speech production. However, if speech characteristics associated with VPD are noted, instrumental assessment can help to identify the source and nature of the deficit or dysfunction.¹⁸ Several types of instrumentation are available for evaluating VPD.

Direct Assessment

Direct instrumental assessment allows an examiner to observe the components of the velopharyngeal mechanism at rest and during functional activities. Frequently reported direct assessment techniques include multiview videofluoroscopy, nasendoscopy, and MRI.¹⁹ Nasendoscopy and videofluorography are the preferred instruments for direct visualization of the velopharyngeal mechanism during speech production.²⁰ Many cleft palate–craniofacial teams in the United States have decided that radiation is no longer needed for evaluating velopharyngeal function and have chosen nasendoscopy as their primary assessment tool.²¹ We will focus on nasendoscopy and videofluoroscopy.

Nasendoscopy and Video Fluoroscopy

Nasendoscopy provides a view of the velopharyngeal mechanism from above, showing the velum, posterior pharyngeal wall, and lateral pharyngeal walls during speech. The adenoid tissue and tonsils, which can either assist or interfere with closure, may be visible. Proponents of nasendoscopy report that it provides extensive information about velopharyngeal closure patterns and the contributions of the velum and pharyngeal walls.²² It has also been shown to be the most appropriate instrumental measure for diagnosing an occult submucous cleft palate and for evaluating velopharyngeal closure after a pharyngeal flap surgery.²³ Reported limitations of nasendoscopy include difficulty identifying small velopharyngeal gaps, difficulty viewing both lateral pharyngeal walls simultaneously, poor visualization because of glare from the light source, interference from adenoid tissue, and obliquity of view.^{13,24,25} Nasendoscopy can be performed by any well-trained professional on the team, but usually the surgeon or the SLP conduct this procedure.

Videofluoroscopy allows examiners to evaluate velopharyngeal movement and timing. Barium is given through the nose, which facilitates visualization of the margins of the velopharyngeal structures. The patient then repeats the target speech sample. Lateral images are obtained to assess velar movement posteriorly and superiorly. This view also shows posterior pharyngeal wall movement. Frontal images are obtained to view lateral pharyngeal wall movement. Because neither view can provide complete information regarding velopharyngeal closure, multiple views should be used to assess the depth of the nasopharynx, velopharyngeal movement, coordination, and the gap size.¹³ Limitations include the need to coordinate with a radiologist, radiographic exposure, and some controversy related to the types and number of images needed for an accurate assessment.²⁵

Regardless of the direct assessment tool employed, images should be measured and reported in a standardized manner to determine the most effective treatment.¹³ Golding-Kushner et al¹³ recommended the use of a ratio scale that estimates the velopharyngeal gap size compared with the size of the velopharyngeal valve at rest. This rating scale is used for both nasendoscopy and videofluoroscopy (Fig. 23-6).

Indirect Assessment

Indirect measures do not facilitate direct visualization of the velopharyngeal structures; they provide information about the functional outcomes of these structures. This allows the examiner to make inferences about the velopharyngeal competence. Common indirect measures include nasometry and aerodynamics assessment,¹⁹ which can be useful in monitoring patients' progress. For example, preoperative and postoperative data can be used to assess improvement.

Nasometry

Nasometry provides a ratio of sound energy transmitted through the nose and mouth during speech. It is an estimate of the average percentage of acoustic energy transmitted through the nose and through the mouth during speech. Nasalance scores are obtained while the speaker repeats words or sentences that, when spoken by normal speakers, contain little nasal resonance. Nasal resonance is expected to be minimal during these productions. Nasalance studies that surpass a predetermined ratio are sometimes used as evidence of VPD. Nasalance scores are most useful in tracking patients with VPD over time and in determining the effectiveness of an intervention at altering oral or nasal resonance for speech.²⁶

Aerodynamic Assessment

Aerodynamic evaluation is useful for assessing nasal airflow and oral air pressure to quantify the effects of VPD on the aerodynamics of speech. A mean oral air pressure of less than 3 cm H₂O and nasal airflow in excess of 300 ml/sec during the production of oral pressure consonants are

Fig. 23-6 The ratio of the velopharyngeal gap size at rest and during speech. The gap size is estimated, compared with the size of the velopharyngeal valve at rest. The gap may be estimated or calculated using computer programs that compute surface area.

considered in the abnormal range. A larger VP opening is usually indicated by lower oral pressure measurements and greater nasal flow measurements. From these measurements, inferences can be made regarding abnormal VP opening during production of pressure consonants; however, the reason it occurs cannot always be determined, especially in a patient with incorrect speech learning.²⁷

Imaging

Various forms of cervical vascular imaging studies, such as CT, MRI (angiogram), and traditional angiography, have been advocated as aids to surgery, because they define the preoperative vascular anatomy. Nevertheless, it is not known whether these studies alter either the performance or outcome of operations on the velopharynx. Many surgeons opt to perform these procedures without any preoperative imaging with good outcomes. Surgeons should be aware of the possibility of anomalous carotid arteries. Visual inspection and palpation intraoperatively guide cautious surgeons to perform safe speech surgery.

NONSURGICAL TREATMENT OPTIONS

Speech Therapy

Speech therapy is indicated to eliminate VPD caused by abnormal speech learning. Compensatory misarticulations in a patient with the ability to achieve velopharyngeal closure, phoneme-specific hypernasality, and phoneme-specific nasal air emission should be treated with speech therapy.

Fig. 23-7 A speech obturator with hard and soft palate components.

Speech therapy can be attempted in patients with borderline or inconsistent velopharyngeal closure. If imaging shows that a patient achieves near-complete velopharyngeal closure, speech therapy may help to improve velopharyngeal closure for speech. Therapy may focus on improving weak or imprecise articulation and improving oral airflow.²⁷ Kuehn et al²⁸ documented some success using continuous positive airway pressure during speech production to treat hypernasality.

Appliances

Prosthetic management may be a solution for treating VPD in a small number of cases. A palatal lift is an option for patients with adequate tissue but poor control of coordination and timing of velopharyngeal movements. A speech bulb, or obturator, is an acrylic mass used for closing velopharyngeal gaps (Fig. 23-7). This is an option in patients without adequate tissue. Prostheses can also be used to provide diagnostic information in patients with variable VPD. If it is unclear whether surgery would provide significant improvement in speech quality, a prosthesis may be used as a temporary tool to help guide surgical decision-making.

SURGICAL TREATMENT OPTIONS AND TECHNIQUES

Surgical Treatment Plan: Algorithmic Approach

Once prospective surgical candidates have undergone nasopharyngoscopy, the results are interpreted by a speech surgeon and SLP. The patient's underlying diagnosis will be placed into the context of the visualized velopharyngeal function to determine a treatment option (Figs. 23-8 and 23-9). Our center uses three options for surgical treatment of VPD: a Furlow palatoplasty, a sphincter pharyngoplasty, and a pharyngeal flap (superiorly based). We tailor the surgery to the specific diagnosis and nasopharyngoscopy findings (Table 23-2). For patients with a cleft palate who underwent a prior straight-line repair and have a small to medium velopharyngeal gap, a Furlow lengthening is selected. The caveat is a significantly short immobile palate. A Furlow procedure in this case would not be sufficient to restore velopharyngeal function, and a pharyn-

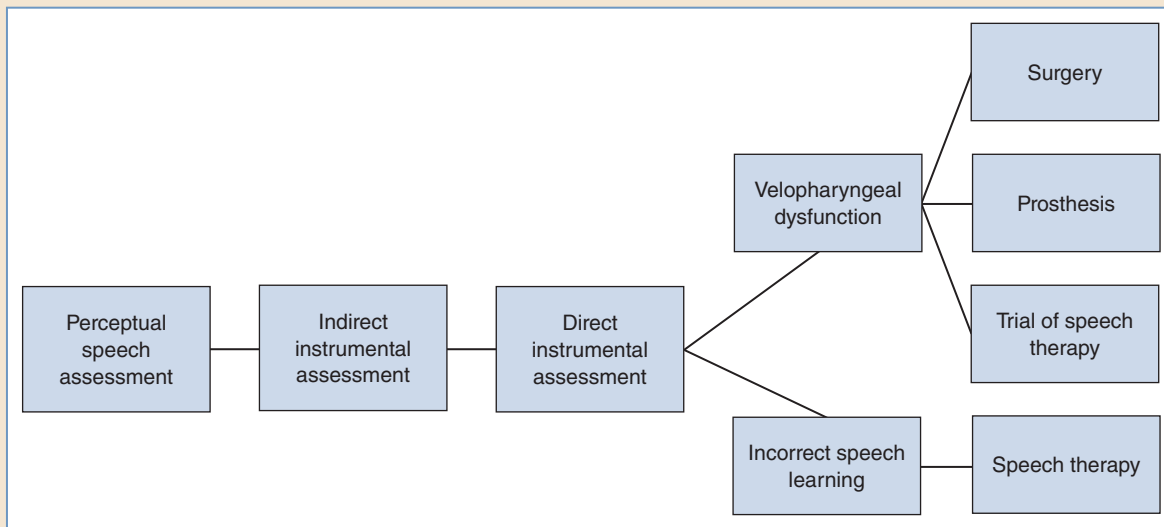

Fig. 23-8 The progression of assessment and treatment of VPD.

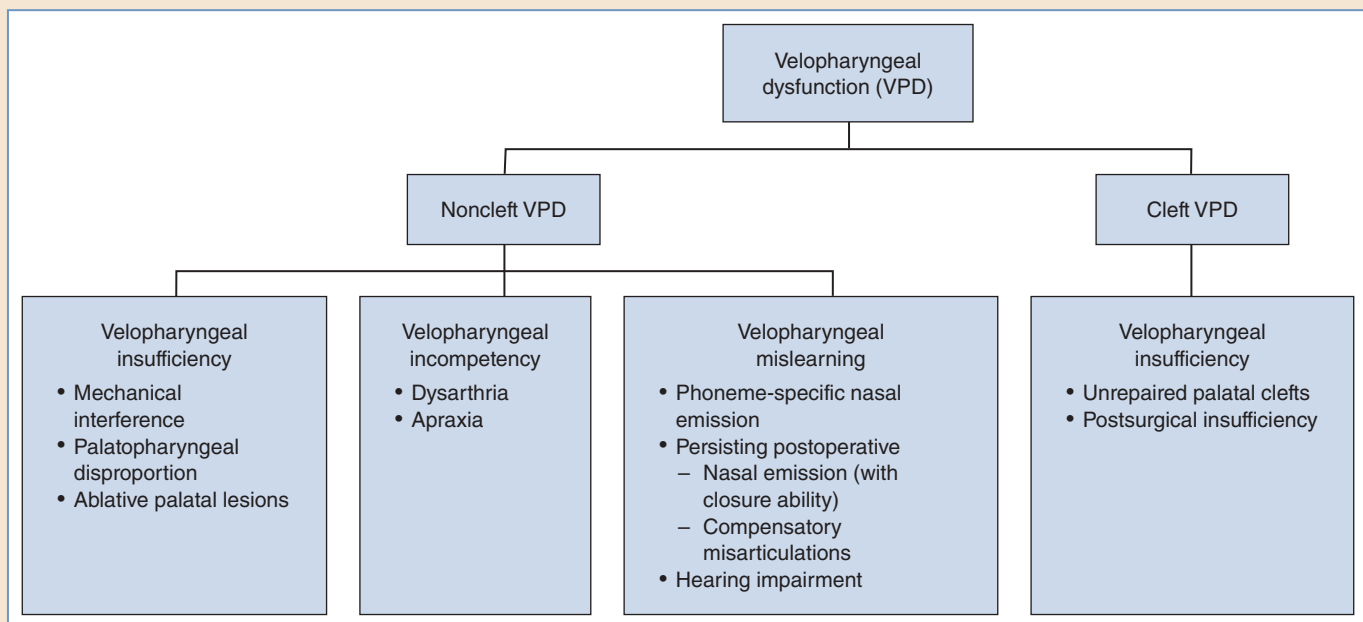

Fig. 23-9 Classification of VPD.

geal flap is chosen. In patients with reasonable palatal length and function but poor lateral wall movement, sphincter pharyngoplasty works well. Finally, medium to large velopharyngeal closure gaps, with either negligible or moderate lateral wall movement, are best treated with a pharyngeal flap. In general, we prefer a Furlow procedure and sphincter pharyngoplasty, whenever possible, over a pharyngeal flap because of the risk of OSA. Furlow palatoplasty and sphincter pharyngoplasty are more physiologic. We have found that following an algorithmic approach to surgical

Table 23-2 Tailoring Velopharyngeal Dysfunction Surgery to the Diagnosis and Scope Findings

	Furlow Palatoplasty	Sphincter Pharyngoplasty	Pharyngeal Flap
Diagnosis	Cleft palate with straight-line repair Submucous cleft palate (nonsyndromic)	Cleft palate, VCF, after adenotonsillectomy, after midface advancement	Cleft palate, VCF, after adenotonsillectomy, after midface advancement
Nasopharyngoscopy	Moderate gap size Palate excursion/movement	Good palate excursion Limited lateral wall movement	Large AP gap Lateral wall motion

selection is advantageous, even in patients with VCF, because of the variety of velopharyngeal closure patterns, and because not all patients have decreased muscle tone.²⁹

Management of the Palatine Tonsils

Many patients who require a surgical procedure to treat VPD have generous-sized tonsils. The approach for managing the tonsils in speech surgery patients differs from that in other patients with standard indications for removal. Although the tonsils may contribute to velopharyngeal closure, removing them would actually increase VPD in the short run. Planned removal approximately 2 months before VPD correction allows increased precision in designing and executing the preferred speech operation.³⁰ This is especially advantageous when a sphincter pharyngoplasty and a pharyngeal flap are indicated. On occasion, tonsils can be large enough to obscure key anatomic landmarks necessary for a successful operation.

Furlow Palatoplasty (Modified)

The various incisions, tissue planes, and limited access associated with performing a Furlow palatoplasty can create confusion for novice surgeons. A consistent approach using the proper instruments and assistance greatly facilitates efficient and successful surgical execution, preventing unnecessary struggle and cervical muscle strain for a surgeon and assistants.

The setup is as important as any other part of the procedure. A microcuffed right-angle endotracheal tube fits properly within the tongue blade groove of a Dingman mouth gag and prevents air leaks that cause bubbling of blood in the oropharynx, interfering with proper visualization. The use of a local anesthetic with epinephrine helps in two ways. The epinephrine induces vasoconstriction in a highly vascular field, and the anesthetic reduces pain-associated elevation of blood pressure, reducing bleeding in the field. The mouth gag is positioned, and the palate is widely injected before the patient is prepared to ensure adequate time for epinephrine to take effect (approximately 10 minutes).

This description of the procedure and approach assumes a prior palatoplasty or a submucous cleft, where the presenting symptom is velopharyngeal insufficiency, usually in patients older than infancy. The procedure is also described for the development of an oral-side myomucosal flap on the left and a nasal-side myomucosal flap on the right.

The initial incisions for a Furlow palatoplasty are made within the hard palate at least a centimeter anterior to the hard palate–soft palate junction, with attempted preservation of a triangular extension of the hard palate. The apex is pointed posteriorly in the midline, providing an anchoring point for hard palate flaps and setup for a V-Y pushback of the hard palate. This maneuver serves to relieve tension on the suture lines in the soft palate. Starting within the hard palate eases the dissection and identification of the greater palatine vessels, whose preservation is important to successful healing because of their vascular supply to the region. Raising the hard palate tissues off the posterior palatine bone also facilitates visualization and suturing of the nasal-side flaps, which will promote success as well.

The incision is started at the lateral margin of the hard palate near the maxillary tuberosity and curved at the maxillary tuberosity laterally behind the dentition to prevent inadvertent injury to the vessels. The cut proceeds anteriorly and laterally and ends at a point about 1 to 2 cm anterior to the maxillary tuberosity. The incision is angled in an AP-medial direction to create a point in the middle of each hard palate flap, and then it is angled posteromedial to the midline, meeting the opposite side again about 1 to 2 cm anterior to the posterior edge of the hard palate margin. (The incision on the hard palate looks like a W.) Fig. 23-10 shows the W-shaped incision on the hard palate, which sets up the V-Y advancement of the hard palate flaps. Subperiosteal dissection should proceed posteriorly to identify the greater palatine vessels. If a midline scar is present, separating the oral mucosa from the nasal mucosa is helpful, leaving the nasal side intact. Preserving the tension associated with an intact nasal scar or uninterrupted mucosa facilitates dissection of the soft palate flaps. Once the hard palate flaps are raised, stay sutures are placed in the apex of the flaps, with a couple throws to assist with retraction.

Once the greater palatine vessels are identified emerging from their posterolateral foramen, dissection should continue around the vessel with a Cottle elevator, including dissection along the posterior edge of the palatal bone as it curves to join the medial aspect of the medial pterygoid plate. Caudal retraction on the hard palate flaps facilitates exposure. The lesser palatine vessel will be encountered lying in a horizontal plane at the junction of the palatine bone and medial pterygoid plate just posterior to the greater palatine vessel. It should be cauterized, because it will tether the flaps, causing undesired tension on transposition. Bleeding can be encountered here as small vessels that perforate the medial pterygoid plate are disrupted, but this will be self-limited. Freeing the soft palate from the medial pterygoid plate eases the dissection of the oral and nasal flaps. An incision is made with a No. 11 blade through all layers of the posterior three quarters of the soft palate in the midline.

With the surgeon standing at the head of the patient, the assistant places a single, fine hook deep to the oral mucosa, close to the start of the incision just made. The hook should not catch the nasal soft tissues. Lateroposterior retraction with a toe-in motion and slight elevation will help to reveal the palatal glands that start at the posterior edge of the palatine bone. The use of monopolar electrocautery on a low, blended setting with an angled Colorado tip can reduce bleeding, enhancing visualization of the targeted plane between the palatal glands and the palatal muscle complex whose fibers run at an angle. A broad dissection plane should be maintained to avoid working in a hole. Proceeding posteriorly, it becomes obvious that the plane comes closer to the oral mucosa as the thickness of the palatal glands diminishes. Once the nasal-side myomucosal flap is separated from the oral-side palatal gland–mucosal flap, an elevator is used to further dissect the tissues off the medial pterygoid in a subperiosteal plane. If a bony cleft is present at the posterior edge of the hard palate, a hockey-stick elevator can be used to strip the nasal floor some degree to release tension.

At this point, the assistant should move to the left side of the surgeon and place the hook in the opposite side with same type of toe-in motion. A Cottle elevator is used to release the tissues off the posterolateral edge of the hard palate toward the medial pterygoid plate to facilitate dis-

Fig. 23-10 W-type incision on the hard palate for a Furlow palatoplasty. **A**, Markings for a modified Furlow palatoplasty. **B**, Completed oral-side myomucosal dissection on the patient's left and oral-side palatal-gland mucosal flap on the right. The nasal-side myomucosal flap on the right is actively being developed. The nasal-side mucosal flap on the left is marked. **C**, Completed nasal-side reconstruction with interdigitating flaps. Note the reorientation of the muscle. **D**, Completed oral closure. Note that there is some raw surface area over the lateral hard palate; this heals secondarily.

section by opening up the planes of dissection. The dissection plane between the muscle complex and the nasal mucosa is the most difficult dissection of the procedure. Constant attention to the angle of the nasal mucosa helps to prevent inadvertent button holes in the thin mucosal flap. The use of face-lift scissors with modified tips, such as Kaye face-lift scissors, also helps with dissection. Bipolar electrocautery assists in stopping the small mucosal bleeders, which is necessary to maintain visualization of the dissection plane. Once posterior and lateral dissection is sufficient,

the nasal mucosa can be stripped off the medial pterygoid and nasal floor in the same fashion as on the right side using a mirror hockey-stick elevator.

Several maneuvers are helpful for mobilizing the tissues in preparation for transposition of the Z-plasty flaps. As mentioned previously, subperiosteal dissection of the nasal-side flaps off the medial pterygoid and nasal floor liberates these flaps quite effectively. If a lateral relaxing incision is used in the soft palate, the tensor veli palatini tendon and hamulus of the medial pterygoid plate will be revealed. Either infracture of the hamulus and/or lysis of the tendon will relieve tension. Additional subperiosteal dissection medial to the incision will finish the release of the soft palate. Last, performing an osteotomy of the posteromedial aspect of the greater palatine foramen with a 2 mm osteotome and liberating the vessel from the canal can relieve additional tension, if present. This maneuver typically provides an additional 2 to 3 mm of medial advancement per side. Experience with the procedure will aid surgical decision-making. Ultimately, patients missing large quantities of tissue, such as those with Pierre Robin sequence, will require more release maneuvers than patients who are born with less severe deformities.

Z-plasty flaps are designed and cut to rotate the muscle complex from their anomalous oblique course, with insertion onto the posterior edge of the hard palate to a transverse, overlapping position. When the dissection is carried out as described, with the right muscle complex attached to the nasal mucosa, the proximal cut is on the right for the nasal Z-plasty closure. Care is taken to make sure this cut is a couple millimeters posterior to the hard palate edge and roughly parallel to the anteriormost fibers of the muscle complex. Leaving a rim of nasal mucosa attached to the posterior edge of the hard palate eases placement of the sutures. Flaps are transposed and sutured while ensuring the mucosa is everted toward the skull base for submucosa-to-submucosa contact. Horizontal mattress sutures can help to achieve proper closure when needed. A small, curved needle (P-2, Ethicon) driven by a long Castroviejo needle holder can be used for placing sutures in this deeper position.

After closure of the nasal side, the oral-side Z-plasty flaps are fashioned with the most proximal cut on the left side to properly rotate the oral-side myomucosal flap to a transverse position. Because the oral-side Z-plasty is not as deep, it is easier to use a larger, thinner needle such as an RB-1 or TF. To kill dead space that naturally occurs as the flaps tent over the nasal closure, the oral closure near the posterior edge of the hard palate can take a bite of the nasal closure on the first pass of a vertical mattress suture. If tension is released off the stay sutures on the hard palate flaps, these flaps can be pushed back in V-Y fashion before the vertical mattress suture is placed. The vertical mattress suture helps to secure the V-Y advancement, relieving tension on the oral Z-plasty closure. The anterior portion of the hard palate flaps is secured to the triangular extension of the midline hard palate. The uvula can be repaired by resecting one of the two uvulas present or by excising the medial half of both and suturing the two halves. Exposed vessels or bone laterally can be covered by splitting the superior pharyngeal constrictor behind the maxillary tuberosity with blunt dissection and allowing the cheek fat pad to herniate into the field. Several sutures can be placed to position the fat that will be mucosalized by secondary intention.

Discussion

The procedure described previously is a modification of the original double-opposing Z-plasty described by Leonard Furlow.³¹ Most surgeons who perform this surgery today use lateral incisions in the hard palate and lateral relaxing incisions in the soft palate. This allows closure of a wider cleft using the Furlow technique. A cleft team working in an interdisciplinary fashion to treat secondary VPD can use nasopharyngoscopy to determine the anatomic derangement of the velopharyngeal mechanism. A subset of patients has a history of a straight-line cleft palate repair; their palates are sagittally deficient and show mild to moderate excursion, with a coronal gap. A Furlow palatoplasty can be performed to successfully treat both VPD and undiagnosed submucous cleft palate in this subgroup.³² Chen et al³³ studied the use of Furlow palatoplasty

for treating secondary VPD related to cleft palate and found it to be effective in 16 of 18 (89%) cases. Their criteria for the Furlow procedure in these patients were:

1. Marginal VPD regardless of age
2. A velopharyngeal closure gap of less than 5 mm
3. A short, scarred palate with an abnormal levator position
4. Good lateral wall movement with a short palate

In a series of 148 patients, a Seattle group² treating secondary VPD patients found a small velopharyngeal gap size to be the most important indicator of success of a Furlow palatoplasty.² In their cohort with a 57% nonsyndromic diagnosis of cleft palate repair (or submucous cleft palate), 73% had resolution of VPD when the gap size was small. As gap size increased, success diminished.

Sphincter Pharyngoplasty

Positioning and Marking

The patient is placed in a supine position on the operating table. After induction of general anesthesia and control of the airway with an oral right-angle endotracheal tube taped in the midline, the table is turned for access to the head. A shoulder roll and gel roll for the head are placed. The neck is extended, and a Dingman mouth gag is inserted. The Dingman has several features of adjustability that can optimize exposure. First, an appropriate-sized blade is selected. This will allow adequate retraction of the tongue without the blade becoming an obstructive force, that is, too large a blade will obscure part of the posterior pharynx. For most cases (in school-age children), a No. 2 blade is appropriate. But this must be tailored to the patient's age and size. Second, when a Dingman is placed, it is inserted until the second row of tooth hooks is secure on the central incisors. Third, the tooth retractors are maintained together in the midline for maximal excursion of the Dingman. Once the Dingman is opened (preoperatively), lidocaine with epinephrine is injected into the posterior soft palate, the posterior tonsillar pillars, and the posterior pharynx, especially along the adenoid pad. The surgeon may attempt to mark the proposed posterior tonsillar pillar flap; however, with the redundancy in the posterior pharynx, this is often futile. The mouth gag is released, and the patient is prepared and draped.

Technique

The Dingman is reopened, with the tongue centered on the blade. If airway pressures increase (through communication with anesthesia), the Dingman is released. This occurs because the Dingman blade and teeth compress the endotracheal tube. A needle cap is placed alongside the endotracheal tube, and the Dingman is reopened. The tube will then be stented open. The lateral Dingman retractors are engaged to help the assistant see the operative field. A red rubber catheter is inserted through a nostril into the posterior pharynx. Then 2.0 silk is used to attach the posterior soft palate/uvular region to the tip of the catheter (Fig. 23-11, *A*). Later in the surgery, this will allow retraction of the soft palate to visualize the superior aspect of the surgical field. The bed is elevated to allow adequate visualization of the inferior posterior pharynx (distal extent of the donor sites). An assistant will provide upward traction on the Dingman handle to further visualize the inferior operative field.

Before an incision is made, the surgeon assesses through visualization and then manual palpation the presence of medially displaced internal carotid arteries. This is a rare phenomenon, seen in VCF, and if found, the surgery may continue, but with adaptation to avoid these structures. Bilateral palatopharyngeus muscle-containing myomucosal flaps will be elevated. Using a toothed forcep, the surgeon grasps the posterior tonsillar pillar, including mucosa and the muscle mentioned previously. With experience, the proper ratio of mucosa to muscle can be grasped (see Fig. 23-11). Using the pinpoint monopolar cautery on a blended cutting current, the myomucosal

Fig. 23-11 Steps of sphincter pharyngoplasty. **A**, Catheter sewn to uvula for retraction; see the eventual position in **B**. The posterior tonsillar pillar is grasped. **B**, Uvula retracted. Posterior tonsillar pillar flaps, each of which includes mucosa and palatopharyngeus muscle, are incised. **C**, Both posterior tonsillar pillar flaps are elevated, and the pharyngeal incision at the adenoid pad is depicted. **D**, Transposition and closure of the posterior tonsillar pillar flaps into the pharyngeal defect. **E**, Closure of the donor sites.

flap harvest begins. The flap assumes the shape of a long pennant. The original grasp of the proposed flap is not released until enough release has been achieved to maintain a consistent ratio of muscle to mucosa. The optimal flap length will allow transposition without tension, with the tip reaching the contralateral lateral wall. To obtain this type of length, the flap is harvested inferiorly along the lateral pharyngeal wall about as far as a Bovie extender will allow. The flap should be elevated to the level of the adenoid pad. An assistant can use a Hurd tonsillar retractor on the lateral pharyngeal wall to facilitate accurate flap elevation. After each flap is elevated, the donor site is closed with 4-0 Vicryl. The soft palate is retracted using the attached red rubber catheter to allow upper field visualization. A transverse incision is made high in the posterior pharyngeal mucosa (typically at the adenoid pad), with some separation of the upper and lower edges, to allow both flaps to occupy the space. The superior pharyngeal constrictor muscle is not incised if at all possible to maintain the inset height of the flaps. The medial vertical myomucosal flap harvest incisions must connect to the horizontal pharyngeal mucosal incision, creating the upper part of a rectangle (Fig. 23-11, *B* through *E*). (This prevents lateral fistulas.) The lateral flap harvest incisions are tailored to release tension as the flaps are transposed.

The next portion of the operation focuses on flap transposition and inset. The first flap (either one) is transposed along the upper raw surface of the horizontal inset incision. Sequential 4-0 Vicryl sutures are placed from the flap base to the tip, attaching the superior mucosal edge to the edge of the adenoid pad. The suture bites through the adenoid pad should be deep, because this tissue is quite friable. The tip of the flap should insert at the junction of the posterior and lateral pharynx. Next, the lower flap is transposed. Again from the base to the tip, the flap is attached to the lower raw edge of the posterior pharyngeal incision. On completion, the tip of this flap should rest at the base of the previously inset flap. The final inset consists of sewing the mucosa of the two flaps together, centrally. The sphincter will be approximately 1 to 1.5 cm. The surgery is completed by releasing the red rubber catheter from the palate and suctioning the stomach with a nasogastric tube. Once the palate is released to its normal position, the flaps cannot be seen. The patient is awakened from anesthesia and extubated.

Discussion

Our preferred method for sphincter pharyngoplasty, as described previously, is a modification of the Hynes procedure, originally described in 1950, further refined by Jackson.³⁴ Orticochea³⁵ also described a version of this operation, but with lower inset of the flaps and limited lateral incisions. The modified Hynes approach allows inset of the sphincter at a more anatomic location with reference to the velopharyngeal mechanism and should prevent lateral fistulas. Some variance and debate still exists regarding flap elevation and inset. One point of variance is the amount of palatopharyngeus muscle harvested in each flap. Most authors espouse taking a good amount of muscle bulk, but how much is really necessary is difficult to quantify. Over the course of his career, Hynes recommended an increasing amount of muscle capture within the myomucosal flaps, including palatopharyngeus, salpingopharyngeus, and even some superior pharyngeal constrictor. A corollary to this is whether the muscle actually functions, contributing dynamically to velopharyngeal closure. The consensus seems to be that the muscles can be functional.^{36,37} Furthermore, what is the optimal size for the sphincter? End-to-end flap apposition has been described.³⁸ Complete overlap of the myomucosal flaps is generally advocated today.³⁴ Is there a way to predict accurately? Some authors recommend splitting the palate for further exposure in the superior aspect of the operative field.³⁸ Is this necessary given the retraction method described previously? Does this maneuver harm the long-term function of the soft palate?

Another area of variance in sphincter pharyngoplasty surgery is the location of the flap inset. Hynes's original description described insetting the flap at the site of velopharyngeal closure. Or-

ticochea's modification³⁵ directed flap inset at a much lower level. Based on a review study, high flap inset leads to better speech outcomes: VPD resolved in 93% of VPD patients who had a high flap inset versus 62% of lower flap inset patients.³⁹ Pigott⁴⁰ corroborated this finding, concluding that the flap should be inset as high as technically possible to bring it into the range of the normal level of the velopharyngeal mechanism.

One of the concerns of any speech operation that reduces the airway dimension is OSA. Nearly all patients undergoing this surgery will have a peak snoring phase of about 2 to 3 months postoperatively, with partial or complete resolution thereafter. Sommerlad²¹ showed mild to moderate OSA using polysomnography after sphincter pharyngoplasty (average patient age 9.3 years, range 3.6 to 18.9 years). Given this range, differences may exist in younger versus older children with regard to OSA after speech surgery.

Finally, is there a role for tonsil/adenoid management in patients who undergo sphincter pharyngoplasty? We advocate tonsillectomy 2 months preoperatively in patients with moderate to large tonsils, as have other investigators.²⁹ Conducting the operation and predicting speech results is much easier in this case. Can tonsils be reduced or removed *during* sphincter pharyngoplasty? Pang and Woodson⁴¹ reported simultaneous tonsillectomy and sphincteroplasty, but this procedure was for OSA.

Pharyngeal Flap

Positioning and Marking

Patient positioning is similar to that described previously for sphincter pharyngoplasty. The patient is prepared and draped in a sterile fashion. A marking pen may be used to outline the superiorly based flap on the posterior pharyngeal mucosa, the base of which rests at the level of the velum (Fig. 23-12, *A* through *F*).

Technique

A Dingman mouth gag may be opened, with tooth retractors in the middle (for full excursion). The device is inserted to the second level of tooth retractors, allowing better posterior pharyngeal visualization. (See the description of sphincter pharyngoplasty for information on managing a compressed endotracheal tube.) As in a sphincter pharyngoplasty procedure, before making surgical incisions, the surgeon visually and manually searches for medialized internal carotid artery or arteries (seen in VCF). With experience, surgeons can estimate proper flap width, but in general, wider is better. Based on a rough estimate, at least two thirds of the posterior pharynx is harvested. Visualization of the anticipated lateral port size further aids in creating the flap width. The surgeon and the assistant on the opposite side grasp the uvula (and/or the soft palate midline). Using a No. 11 blade, the soft palate is split, full thickness, in the midline anteriorly to the hard-soft junction. The flap harvest is initiated. The assistant lifts the handle of the Dingman upward to allow a view deeper into the inferior posterior pharynx. Using blended cutting currents with monopolar cautery, flap elevation is initiated, including mucosa and superior pharyngeal constrictor muscle. Visualization of the prevertebral fascia during the dissection indicates appropriate flap thickness. The flap is elevated superiorly until it can be transposed and contacts the caudal edge of the hard palate without tension. The lower portion of the donor site is closed with 4-0 Vicryl.

Bilateral nasal mucosal pennant flaps are elevated. The posteromedial cut edge of the soft palate is grasped with a single hook and reflected laterally, exposing the nasal mucosa. The nasal mucosa is incised to create a triangle with the base (widest part) along the posterior soft palate. The delineated triangle flap is elevated so that it transposes posteriorly, containing mucosa and subcutaneous fat. This is done bilaterally. These flaps will cover the raw surface of the pharyngeal flap after the initial inset.

Fig. 23-12 Steps of superiorly based posterior pharyngeal flap. **A**, Soft palate is opened in midline from uvula to posterior hard palate. **B**, Catheters will be used to gauge lateral “port” size. Soft palate is retracted. The superiorly based posterior pharyngeal flap is marked, to include mucosa and superior pharyngeal constrictor muscle. **C**, Bilateral nasal mucosa pennant flaps are elevated and the posterior pharyngeal flap is brought into the soft palate. **D**, The pharyngeal flap has been inset. The nasal mucosa pennant flaps are transposed to cover the raw surface of the transposed pharyngeal flap. **E**, Final oral and nasal mucosal closure. **F**, The donor site is closed primarily. **G**, The use of 14-gauge red rubber catheter (shown in blue) to modulate port size.

The flap is inset and the port size contoured. Using mattress sutures of 4-0 Vicryl, the flap inset begins in the midline near the hard-soft palate junction. This is the last opportunity to adjust flap tension. Progressing laterally, from the tip of the flap toward its base, sequential mattress sutures are placed along each side of the flap to the lateral soft palate to secure the flap inset. Bilateral 14 Fr red rubber catheters are placed transnasally and in each lateral pharyngeal location (Fig. 23-12, G). The catheters do not indicate the final port size, but aid in visualization and overall port size adjustment. As the sequential flap mucosa to lateral soft palate nasal mucosal sutures are placed, a general idea of port size can be determined. Most of the port size is created at this point, where visualization is better. The final port size can be adjusted after the lining is closed. This varies from patient to patient; however, 1 to 1.5 cm is a rough estimate. The previously raised bilateral soft palate nasal mucosal pennant flaps are transposed. The key suture is placed to unite the tips of the flaps and to anchor them to the base of the flap (at the posterior pharyngeal wall). The flaps are closed distal to proximal, grasping a bite of flap muscle to create an adherence. Closure of the midline to the hard-soft junction is completed. The final lateral port adjustments can be made. The flap donor site is closed, up to the base of the transposed flap. If postoperative airway obstruction is a concern, the surgeon can place a nasopharyngeal airway (or two). The stomach is suctioned with a nasogastric tube, and the Dingman is removed. The patient is then awakened from anesthesia and extubated.

Discussion

The pharyngeal flap surgery detailed previously is a modification of the superiorly based pharyngeal flap, originally described by Schönborn in 1876⁴² and popularized by Padgett.⁴³ The goal of this procedure is a midline subtotal airway obstruction, with improved velopharyngeal function, without airway compromise. Several aspects of this procedure have been and continue to be discussed.

First, should the flap be inferiorly or superiorly based? The literature on this issue is mixed. Proponents of an inferiorly based flap claim that scarring in the posterior pharynx will have a cephalad pull (because of the orientation of the raw surface on the nasal aspect of the flap, pulling it up into a more optimal position with the velopharyngeal mechanism).⁴⁴ A disadvantage is length limitation. A superiorly based flap can be long and tailored to the port size as needed. Many studies have shown function is equivalent; however, Wattanawong et al⁴⁴ showed improved correction of VPD with an inferiorly based flap with a head-to-head comparison.

Another area that continues to prompt discussion is the proper flap width. Many advocate making the widest flap possible (without creating complete airway obstruction). Shprintzen et al⁴⁵ recommended tailoring the width of the flap based on the amount of lateral wall movement during a nasopharyngeal examination. Others have supported this idea.⁴⁶ Although this concept is appealing theoretically, accurate practical application in the operating room can be difficult. Another approach to flap width is a "short wide flap." Some think this type of flap is less prone to inferior scarring and can truly create a subtotal obstruction of the nasopharynx, an outcome potentially desirable in patients with an adynamic velopharyngeal mechanism such as those with VCF.

A further refinement of superiorly based pharyngeal flap surgery is the lateral port control. Hogan⁴⁷ is credited with the method for adjusting port size. Based on findings from prior studies on oropharyngeal airway flow dynamics, he recommended controlling lateral port size during surgery with a 4 mm² catheter placed in each nasal orifice. These studies showed an increase in nasal airflow between 10 to 20 mm² and frank nasal air escape of more than 20 mm². The specific aspect of superiorly based pharyngeal flap surgery that controls the lateral port size is the use of soft palate nasal mucosal pennant flaps. When sequentially sutured to the lateral aspect of the pharyngeal flap, the mucosal pennant flaps can be used to progressively narrow the lateral port orifice.

The early descriptions of posterior pharyngeal flap surgery did not include reference to coverage of exposed raw surfaces during surgery.⁴⁸ Since that time, refinements to this surgery have included closure of the donor site, which decreased postoperative pain and scarring. With the use of an unlined pharyngeal flap, practitioners noted undue horizontal contracture, which predisposed to postoperative continuance of VPD. Bilateral nasal soft palate pennant flaps provide mucosal lining to the raw surface on a superiorly based flap, thus decreasing uncontrolled contracture.⁴⁹

For many years the pharyngeal flap has been considered the benchmark for surgical correction of VPD. However, it has also been known to place the patient's airway at risk, both in the immediate postoperative period and in the long term, with the potential for OSA. Most patients will snore in the immediate postoperative period, because of both the flap itself and early postoperative swelling. Usually by about 3 months after surgery, most or all of the snoring will resolve. However, the long-term airway findings are most important. Liao et al⁵⁰ used polysomnography to assess the risk of OSA in adults and children after pharyngeal flap surgery. They found a 93% prevalence of some level of OSA more than 6 months after surgery, with 58% of patients in the moderate to severe category. Flap width was not an independent variable leading to the development of OSA. This rate of OSA is much higher than in many of the prior studies.⁴⁹⁻⁵¹ Lesavoy et al⁵² showed a 38% rate of airway obstruction based on an observational obstruction scale and a limited sleep study analysis in the early postoperative period. Over time the obstructive symptoms subsided and 2 of 32 patients had severe OSA on polysomnography after 3 months. The authors concluded it was necessary to accept transient airway obstruction to achieve velopharyngeal competence. Ysunza et al⁵³ reported on a series of 571 patients who underwent superiorly based pharyngeal flap procedures. Eighteen had obstructive symptoms, with 15 (2.6%) scoring *severe* on polysomnography.

There is currently no consensus on the severity of long-term airway obstruction in pharyngeal flap surgery. One difficulty is the variability with which this outcome has been studied. A polysomnogram performed several months after surgery and scored by a trained pediatric sleep specialist would be the benchmark for measuring long-term airway impairment. Very few studies have achieved this level of detail.

Another area of debate regarding pharyngeal flaps is whether the flap is dynamic in velopharyngeal functioning. Most agree that the most significant aspect of functioning within the velopharyngeal mechanism in patients who have had a pharyngeal flap is the lateral wall motion. However, Broadbent and Swinyard⁵⁴ performed an electromyographic study showing variable amounts of muscle activity within posterior pharyngeal flaps.

Pharyngeal Augmentation

Alloplastic Materials

A subset of patients with mild VPD and a small gap on velopharyngeal closure have unsuccessful speech therapy. The size of the gap does not substantiate the use of Furlow lengthening, sphincter pharyngoplasty, or a pharyngeal flap. A variety of methods of posterior pharyngeal wall augmentation have been employed to treat this particular group of patients. Several alloplastic materials have been used, including silicone, Teflon, polyethylene, and Proplast. Data are mixed regarding the efficacy of these materials in treating VPD.⁵⁵ Issues have been reported of caudal migration of implants along the prevertebral fascia, which nullifies the functionality of the implant. As with any prosthetic material, extrusion and infection are risks. A study on the use of Proplast I showed promising results for correction of VPD, with a reasonable safety profile.⁵⁶ Another promising method using alloplastic material is the injection of calcium hydroxylapatite (Radiessse). A review study showed good tolerance of the material with improved velopharyngeal function.⁵⁷

Fig. 23-13 Posterior pharyngeal augmentation with a rolled flap.

Autologous Materials

Several methods involving autologous material have been used for VPD. Autologous fat injection has showed mild improvement in VPD; however, it is prone to resorption. Rolled dermis inserted in to the Passavant ridge region has had a similar profile. Last, posterior pharyngeal augmentation with a rolled flap has been evaluated. A superiorly based posterior pharyngeal flap is created and rolled on itself (Fig. 23-13). The base is sutured near the tubercle of the atlas. This flap has not been shown to compromise the airway, but it has not led to notable speech outcome improvement.⁵⁸

POSTOPERATIVE CARE

Patients who have had speech surgery must be treated as having a delicate airway. Swelling, bleeding, and oral secretions may be difficult for the patients postoperatively. They require at least overnight monitoring in a step-down unit or a unit that can provide continuous oxygen monitoring. Some patients need a nasal airway placed carefully and under direct vision by the surgeon in the operating room for temporary maintenance of the airway until they are more awake. Occasionally, it is useful to suture this nasal airway to the septum to prevent it from accidental dislodgement. IV fluids are continued until patients are able to drink adequately. Hard foods and other hard objects should not be placed in the mouth. The patient is limited to a strict liquid and pureed diet for the next 3 to 4 weeks postoperatively. Pain is controlled with acetaminophen and ibuprofen alone, and narcotic pain medications are given for breakthrough pain. Having all medications in a liquid oral formulation is helpful. Patients can be discharged home on the first postoperative day if their pain is controlled, they are drinking, urine output is adequate, and they have had no untoward events noted on their continuous oxygen monitors. A routine follow-up is scheduled for 2 weeks postoperatively. Parents and patients are counseled that speech may worsen before it improves. Patients may initially snore before the swelling improves.

Postoperative Speech Therapy

Postoperative speech therapy is delayed until the velopharynx recovers from surgery, and the surgeon deems it to be healed enough to be stressed by speech therapy. Typically, this occurs

approximately 6 weeks after the procedure. Parents are counseled that their child's speech may not be improved immediately, but some tonal difference should be noted initially. As swelling continues to improve, and as patients are able to participate in more active speech therapy, it is generally expected that speech will improve over time.

TREATMENT OUTCOMES

Several retrospective studies and some prospective analyses on the outcomes of sphincter pharyngoplasty and pharyngeal flap have been conducted. Sie et al⁵⁸ retrospectively studied patients with repaired cleft palates and syndromic diagnoses who underwent sphincter pharyngoplasty for VPD. Twenty of 24 (83%) had complete or significant resolution of VPD on perceptual speech assessment, and six (25%) had residual VPD. Of these six patients, three had a secondary surgery and complete resolution of VPD. In cases of failed sphincter pharyngoplasty, the cause appears to be related to the level of insertion of the myomucosal flaps. Flaps inserted too low on the posterior pharynx (lower than the CI–adenoid pad region) tend to result in inadequate velopharyngeal closure postoperatively.⁵⁹ Others have studied the ability of the sphincter pharyngoplasty to achieve dynamic function, concluding that nearly all newly created sphincters will have dynamic function, but movement of the sphincter has no influence on postoperative speech outcomes.^{37,38}

Pharyngeal flap surgery has been effective in treating VPD in an isolated retrospective analysis. In a study of 60 patients with a pharyngeal flap,⁵⁴ 78% achieved normal speech, 18% were hyponasal, and 3% had persistent hypernasality.⁴⁹ Pharyngeal flap surgery has been shown to be effective in syndromic patients as well. In a retrospective analysis of patients with VCF with VPD who had a pharyngeal flap, Swanson et al⁶⁰ found an 88% correction rate, with 1 of 33 showing signs of sleep apnea.

Multiple studies have compared sphincter pharyngoplasty and pharyngeal flap surgery for speech outcomes. The VPD Surgical Group reported on a large, multiinstitutional randomized trial of sphincter pharyngoplasty and pharyngeal flap for treating secondary VPD.⁶¹ They found no difference in speech outcomes. This work corroborated earlier studies, including a large series (168 patients) that showed similar outcomes for speech correction (70% to 75%) with either technique.^{62,63} However, the comparison studies showed a trend toward increased airway obstruction in pharyngeal flap patients, compared with sphincter pharyngoplasty patients, and a small percentage chance of overcorrection (hyponasality).

Complications

The basic goals of speech surgery are to improve, if not normalize, VP function and prevent long-term OSA. Noted complications of Furlow palatoplasty, sphincter pharyngoplasty, and pharyngeal flap revolve around these two goals. In the acute setting, bleeding can occur. Most postoperative bleeding is self-limited but can require returning the patient to the operating room if it is persistent and/or threatens airway function. The health care team should be vigilant to ensure that patients do not develop an acute airway obstruction in the immediate postoperative period and are monitored in an intermediate care setting. Pharyngeal flap patients (and Furlow palatoplasty patients) are most at risk for this impairment. An intraoperatively placed nasopharyngeal airway can ameliorate this problem. Subacute complications include dehiscence and fistula formation. Long-term speech complications include persistent velopharyngeal dysfunction, as evidenced by hypernasality or hyponasality. After about 3 months, patients should be evaluated for symptoms and signs of persistent airway obstruction. They may require polysomnography to rule out OSA if indicators are present, such as persistent snoring, daytime somnolence, irritability, and an inability to concentrate.

FUTURE DIAGNOSTIC AND TREATMENT MODALITIES

Robotic Surgery

The Children's Hospital of Philadelphia recently conducted a feasibility study wherein they used cadaver heads and a robotic telemanipulator to perform pharyngeal flaps.⁶⁴ They noted the learning curve was steep, but the setup was ergonomic. Visibility of the ports was simplified by the use of a 30-degree endoscope. In the future, with improving robotic technology it may be possible to perform these technically demanding operations under better ergonomic circumstances with better visualization.⁶⁴

Magnetic Resonance Imaging

Dynamic MRI of the velopharynx may be reformatted to simulate endoscopy. This technology has not been used in a widespread fashion yet, but may be helpful in the future as a type of virtual endoscopy or as an adjunct procedure.

KEY POINTS

- A multidisciplinary approach is best for patients with VPD.
- VPD may have either structural or neurologic causes.
- Orofacial cleft patients with a history of a repaired cleft palate are the most common group to present with VPD in school-age children.
- Patients with a VCF abnormality may have aberrant carotid artery anatomy.
- A palpable notch at the junction between the hard and soft palate, a zona pellucida, and a bifid uvula may be signs of a submucous cleft palate.
- Both sphincter pharyngoplasty and a pharyngeal flap carry a risk of OSA, with a greater risk with pharyngeal flap.
- A comprehensive examination and speech workup should be completed by an interdisciplinary team that includes a surgeon and an SLP before speech surgery is considered.
- Patient diagnosis, the severity of VPD, and findings on NP examination drive the selection of the speech surgery procedure.
- Superiorly based pharyngeal flap use is most popular, but the literature supports using either an inferior- or a superior-based flap for treating VPD.

Continued

KEY POINTS (continued)

- The pharyngeal flap width can be tailored based on the amount of lateral wall motion on nasopharyngeal examination.
- With good palate excursion and poor lateral wall motion, sphincter pharyngoplasty is a good treatment for VPD.
- In patients who have had a sphincter pharyngoplasty, myomucosal flaps have been shown to be dynamic.
- Surgical inset of transposed palatopharyngeus flaps in sphincter pharyngoplasty should be at the level of the C1-adenoid pad.
- Most secondary VPD is nonsyndromic and related to a history of cleft palate repair, and the next most common cause is a 22q deletion.

Craniosynostosis

Christopher R. Forrest • Phuong D. Nguyen • Darren M. Smith

To the inexperienced, craniosynostosis might seem like a kaleidoscope of unusual craniofacial dysmorphology managed only by craniofacial surgical specialists. However, it can be defined more simply as a premature fusion of one or more cranial sutures that leads to characteristic and specific deformities of the cranial vault. It can occur in the postnatal period, but most cases develop in utero and may be diagnosed at birth. Craniosynostosis can be an isolated event or associated with a syndrome.

Functional implications of craniosynostosis are related to the dynamic growth of the craniofacial skeleton and depend on the number of involved sutures and the presence of a syndrome. However, in isolated cases, they focus primarily on neurologic and psychosocial issues related to the aesthetic deformity. Goals of surgical treatment are to improve shape, form, and function and to expand cranial vault volume to accommodate ongoing brain growth.

Management is multidisciplinary, provided by a skilled team of specialists. It should be the domain of tertiary or quaternary care centers with high volumes. This chapter discusses implications and management options for patients who present with craniosynostosis.

HISTORICAL AND ETIOLOGIC ASPECTS

Although several Greek and Roman authors have referred to the condition of craniosynostosis, the pathology was not recognized until Vesalius¹ published *De Humani Corporis Fabrica Libri Septem* in 1543 (Fig. 24-1). This publication provided clear illustrations of brachycephalic and plagiocephalic skulls.

In 1830 Otto² proposed that a consequence of premature suture fusion was compensatory cranial expansion along another trajectory and was the first to use the name *craniosynostosis*. However, the bulk of the credit went to Virchow,³ a German anatomist at the turn of the century, who described *Virchow's law*. This essentially states that the observed deformities occur as a result of “cessation of growth across a prematurely fused suture,” with “compensatory growth” along non-fused sutures in a direction parallel to the affected suture, causing obstruction of normal brain growth (Fig. 24-2). This law is a very useful tool for understanding and establishing the diagnosis of craniosynostosis.

Fig. 24-1 Image from Vesalius' *De Humani Corporis Fabrica Libri Septem* (published in 1543) demonstrating cranial dysmorphology caused by craniosynostosis. (Courtesy of the British Library.)

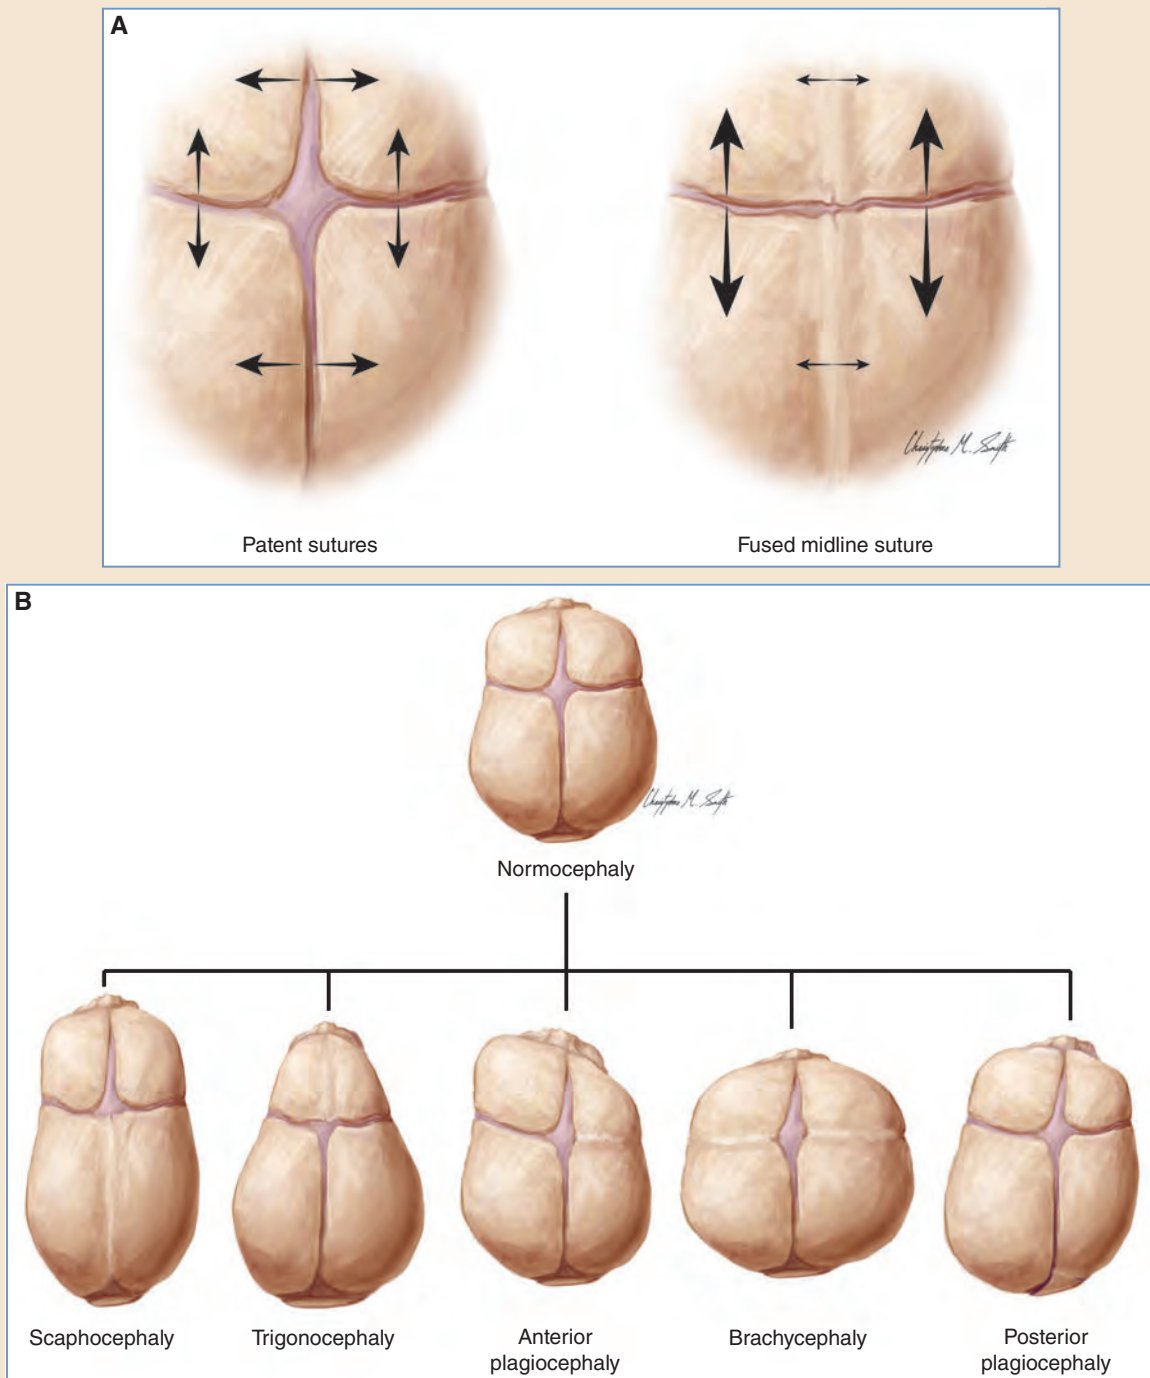

Fig. 24-2 Virchow's law of skull growth. **A**, The cranial sutures allow expansion and growth of the skull at right angles to the sutures (*left*). When a suture is fused, bone expansion ceases in a direction perpendicular to the fused suture, and compensatory expansion occurs in the opposite direction because of the presence of the patent sutures (*right*). **B**, This leads to predictable deformities of the calvarial vault that are diagnosed as single-suture craniosynostosis in a clinical examination. Cases of multiple-suture involvement and syndromic craniosynostosis are more challenging and require radiographic investigation.

Fig. 24-3 Embryology of the craniofacial skeleton. Endochondral bone makes up most of the skull base, and membranous bone forms the cranial vault.

Embryology

The skull is a unique and dynamic structure composed of the neurocranium (brain case) and viscerocranium (bones of the lower face) that appear embryologically at 6 to 8 weeks and begin to ossify by 12 weeks' gestation (Fig. 24-3). The components of the neurocranium are classified as *cartilaginous* (skull base) and *membranous* (skull plates), according to the method of bone formation. Endochondral ossification occurs after the development of a cartilaginous precursor and forms the sphenoid, occipital, and petromastoid portion of the temporal bone and ethmoid bones. Intramembranous ossification occurs from a layer of mesenchyme under the dermal mesenchyme and above the meninges as a series of centers that coalesce radially to form the parietal, frontal, and squamous portions of the temporal bones, with input into the frontal bone by neural crest cells. Sutures form between the ossifying plates of bone, and fontanelles (soft spots) form where the three sutures come together.

Anatomy

In infants, the calvarial vault comprises two parietal bones, two frontal bones, two temporal bones, and the occipital bone. These are joined by four major sutures (coronal, metopic, sagittal, and lambdoid) and multiple minor sutures (squamosal, sphenofrontal, sphenosquamosal, sphenoparietal, parietomastoid, and occipitomastoid) (Fig. 24-4). The occipital and temporal bones are compound bones with multiple ossification centers that indicate fusion of more than one embryonic element. Occasionally, extra bones form within sutures known as *wormian* or *intrasutural*

Fig. 24-4 The anatomy of an infant skull, showing the major sutures, the minor sutures, and the fontanelles.

Fig. 24-5 This CT scan shows the presence of wormian (intrasutural) bones in the lambdoid suture.

bones (Fig. 24-5). These irregular, isolated bones often arise in the course of the lambdoid suture and may be a marker for numerous diseases. Major landmarks of the skull are the bregma, which is the point of intersection between the sagittal and coronal sutures, and the lambda, which is the posterior point of intersection of the sagittal and lambdoid sutures.

Cranial sutures are a type of fibrous joint (synarthrosis) that allows small amounts of movement and contribute to the elasticity and compliance of the skull. This facilitates molding of the head during passage through the birth canal and rapid growth of the skull in the first few years of life. Sutures are signaling centers and regulate the balance between proliferation and differ-

entiation of osteogenic precursor cells during the first few years of life. Cartilaginous synchondroses are the equivalents on the skull base but are formed differently because of endochondral ossification.

The human calvarial vault has six fontanelles, which form where three sutures come together (see Fig. 24-4). They consist of two unpaired (anterior and posterior) and two paired (anterolateral or sphenoid and posterolateral or mastoid) fontanelles. The fontanelles are nonossified membranous areas that allow rapid stretching and deformation of the cranium as the brain expands. The posterior fontanelle usually fuses by 3 months of age, and the anterior fontanelle is the last to close, usually by 18 months of age. The fontanelles can bulge with underlying intracranial pathology such as increased pressure. Large, confluent fontanelles may be seen in craniofacial dysostosis syndromes. However, absent or small fontanelles are not necessarily a cause for alarm in the absence of other pathology or developmental delay.

Growth and Development

According to the functional matrix hypothesis proposed by Moss and Salentijn,⁴ bones do not grow but are grown: “form follows function.” This dictates that the growth of the skeleton is a secondary response to the demands of the related functional matrices, which, in the case of the calvarium, is very much influenced by the growth of the brain. Human brain growth is robust, tripling in size by 1 year of age, and reaches 85% of adult size by 3 years of age.⁵ Primary growth of the brain results in a stimulus for secondary growth of the sutures and synchondroses, with resultant deposition of bone on the sutural edges. This is the predominant form of calvarial growth until about 4 years of age, when the head circumference is approximately 90% that of an adult size. Subsequent growth of the skull is less dependent on sutural expansion and is appositional in nature, with bone deposited on the ectocranial and endocranial surfaces, resulting in an increase in bone thickness and expansion of the medullary space (and formation of the diploe). Cranial sutures fuse in a predictable manner from front to back and from lateral to medial, with the metopic suture closing by 8 to 9 months of age.⁶ The remaining sutures are patent until the third decade of life, and they fuse in the following sequence: sagittal suture (22 years of age); coronal suture (24 years of age); lambdoid suture (26 years of age) and squamosal suture (after 60 years of age).

CLASSIFICATION FOR CRANIOSYNOSTOSIS

Myriad Greek terms are used to describe the head shapes associated with craniosynostosis but do not provide a useful methodology for classification. Craniosynostosis is best categorized according to the number of involved sutures (single or multiple), the anatomic location (sagittal, metopic, unilateral or bilateral coronal, lambdoid, or minor sutures), and whether it is associated with a recognized syndrome (Box 24-1). Craniosynostosis has been recognized as a component of more than 180 syndromes, but the most common are Apert, Crouzon, Pfeiffer, Saethre-Chotzen, and Muenke syndromes.

EPIDEMIOLOGY, NOMENCLATURE, AND INCIDENCE

Craniosynostosis has an incidence of 1 in 2000 to 1 in 5000 newborns.^{7,8} Most (85%) are categorized as single-suture and nonsyndromic. The suture most often involved is the sagittal suture, causing sagittal synostosis. More recently, it appears that metopic synostosis has displaced unilateral coronal synostosis (range 1 in 10,000 to 1 in 15,000 live births) as the second most common form in Europe and the United States.^{9,10} Reported cases of lambdoid synostosis may have been overestimated, because posterior plagiocephaly may actually have been attributed to deforma-

Box 24-1 Classification of Craniosynostosis**Anatomic****Single-suture**

Sagittal
Metopic
Unicoronal
Lambdoid
Minor suture (frontosphenoid,
zygomaticotemporal)

Multiple-suture

Any combination possible, usually bicoronal

Cause**Primary**

Nonsyndromic
Scaphocephaly (sagittal)
Trigonocephaly (metopic)
Anterior plagiocephaly (unicoronal)

Posterior plagiocephaly (lambdoid)
Turribrachycephaly (bicoronal)
Oxycephaly (delayed bicoronal)
Syndromic (more than 180 syndromes with
craniosynostosis)
Apert syndrome
Crouzon syndrome
Pfeiffer syndrome
Jackson-Weiss syndrome
Carpenter syndrome
Muenke syndrome
Saethre-Chotzen syndrome

Secondary

Biomechanical (shunt)
Bone metabolic disorders
Nutritional
Oxycephaly

Table 24-1 Classification and Incidence of Craniosynostosis

Name	Shape	Etiologic Factors	Incidence
Scaphocephaly	Keel- or boat-shaped	Sagittal synostosis	1 in 2500 ^{7,8}
Dolichocephaly	Long and narrow		
Trigonocephaly	Triangular	Metopic synostosis	1 in 10,000 ^{9,10}
Plagiocephaly	Asymmetrical, anterior or posterior flattening	Unilateral coronal synostosis Lambdoid synostosis	1 in 15,000 ^{9,10} 1 in 100,000 ^{11,70}
Turriccephaly	Tall or tower	Bilateral coronal synostosis	Variable with syndromes
Brachycephaly	Short, broad		
Turribrachycephaly	Tall, short, broad		
Oxycephaly	Conical or pointed skull, delayed-onset	Bilateral coronal synostosis	Rare
Kleeblattschädel	Cloverleaf, trilobar	Pansynostosis	Rare

tional forces. True lambdoid synostosis is rare, with an incidence of 1 in 100,000 live births.¹¹ In single-suture, nonsyndromic craniosynostosis, the symmetrical (sagittal and metopic) forms have a male predominance, and the asymmetrical (unicoronal) forms have a female predominance.

The nomenclature for the cranial deformities associated with craniosynostosis can be confusing (Table 24-1). The names are descriptive only; skull dysmorphism also can result from non-synostotic pathology (for example, scaphocephaly from prematurity).⁹

Syndromic craniosynostosis is relatively rare, with 1 in 25,000 to 1 in 100,000 infants affected.⁷ More than 180 different syndromes are associated with craniosynostosis^{9,12,13} (Table 24-2).

Table 24-2 Nomenclature of Craniosynostosis

	Apert Syndrome	Crouzon Syndrome	Pfeiffer Syndrome	Muenke Syndrome	Saethre-Chotzen Syndrome	Craniofrontonasal Syndrome
Gene mutation	<i>FGFR2</i>	<i>FGFR2</i>	<i>FGFR1</i> <i>FGFR2</i>	<i>FGFR3</i> : Pro250Arg ²⁰	<i>TWIST</i>	<i>EFNB1</i>
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant	Autosomal dominant	X-linked
Incidence	1 in 70,000 ⁷⁸	1 in 65,000 ^{71,80}	1 in 100,000 ⁸²	1 in 30,000 ^{85,86}	1 in 25,000 to 1 in 50,000 ⁸³	1 in 100,000 to 1 in 120,000 ⁸⁸
Skull morphology	Bilateral coronal synostosis	Bilateral coronal synostosis	Bilateral coronal synostosis, cloverleaf skull in type 2 Pfeiffer	Unilateral or bilateral coronal synostosis, macrocephaly	Unilateral or bilateral coronal synostosis, metopic synostosis	Unilateral or bilateral coronal synostosis
Facial features	Proptosis, cleft palate, high-arched palate, partial adontia, midface hypoplasia	Proptosis, hypertelorism, strabismus, mandibular prognathism, midface hypoplasia	Proptosis, hypertelorism, supernumerary teeth, midface hypoplasia	Proptosis, hypertelorism, high-arched palate, mild midface hypoplasia	Lid ptosis, ear anomalies, low frontal hairline, midface hypoplasia	Hypertelorism, broad nasal bridge, bifid nasal tip; rarely, cleft lip and/or palate (females more severely affected), dry frizzy hair
Limb anomalies	Syndactyly (second through fourth digits), radiohumeral fusion, progressive tarsal bone fusion	Tarsal bone fusion, symphalangism	Broad toes and thumbs, tarsal bone fusion, elbow ankylosis, elbow synostosis, cutaneous syndactyly	Brachydactyly of hands and feet, symphalangism, Klippel-Feil cervical anomaly	Cutaneous syndactyly, hallux valgus, duplicated distal phalanx of the hallux	Asymmetrical lower limb shortness, broad hallux, joint laxity, cutaneous syndactyly, grooved nails
Neurocognitive impairment	Severe intellectual disability and/or developmental delay, conductive hearing loss	Intellect normal, conductive hearing loss	Intellect normal in Pfeiffer type 1, intellectual disability and developmental delay in Pfeiffer type 2 and 3, conductive hearing loss	Intellectual disability and/or developmental delay, low-frequency sensorineural hearing loss	Intellect normal; developmental delays common in those with gene deletions; conductive, mixed, and profound sensorineural hearing loss	Normal intellect in >50%, 10% to 50% with developmental delay, occasionally learning difficulties (mild), sensorineural hearing loss

Genetics

A clinical and molecular genetic assessment is a crucial part of managing infants who present with craniosynostosis. A genetic association was first reported in 1993 in a family cohort in Boston and was linked to a mutated copy of *MSX2*, a homeobox gene thought to function in inductive tissue interactions during embryogenesis and caused by a single amino acid substitution.¹⁴ Boston-type craniosynostosis is a highly penetrant autosomal dominant form of syndromic craniosynostosis that is rarely seen outside the original cohort, but its importance in demonstrating

the role of genetics cannot be overstated. Subsequently, mutations in the *fibroblast growth factor receptor* (*FGFR*) genes, *TWIST1* genes, and *ephrin B1* (*EFNB1*) genes were found to be responsible for most syndromic craniosynostosis cases, although the field is dynamic and new mutations are identified each year.^{7,12} The FGF family is composed of 22 highly conserved proteins that are important in regulating cell proliferation, differentiation, and migration. *TWIST1* is a transcription factor that plays an important role in specifying and maintaining cell identity. *EFNB1* is a protein-coding gene involved in cell adhesion and functions in the development of the nervous system. Chromosomal alterations are responsible for 10% to 30% of syndromic craniosynostoses.¹³ In contrast, nonsyndromic, single-suture synostoses appear to have less correlation with genetic mutation, though recent evidence suggests increased *RUNX2* expression may represent a transcriptomic signature for a subset of single-suture craniosynostosis cases.¹⁵

More than 180 craniosynostosis syndromes have been identified, with more than 60 different genetic mutations.¹⁶ Most of these mutations occur in *FGFR2*. Eight fibroblast growth factor receptor-mediated craniosynostoses have been reported:

1. Apert syndrome (*FGFR2*)
2. Crouzon syndrome (*FGFR2*)
3. Jackson-Weiss syndrome (*FGFR2*)
4. Muenke syndrome (*FGFR3*)
5. Crouzon syndrome with acanthosis nigricans (crouzonodermoskeletal syndrome) (*FGFR3*)
6. Pfeiffer syndrome (*FGFR1* and *FGFR2*)
7. Beare-Stevenson syndrome (*FGFR2*)
8. *FGFR2*-related isolated coronal synostosis

More than 100 distinct mutations in *TWIST1* have been identified as causative of Saethre-Chotzen syndrome.¹⁷ Craniofrontonasal dysplasia is caused by mutations in the *EFNB1* gene.

PATHOPHYSIOLOGY

Early theories of the pathophysiology of craniosynostosis included infection, metabolic conditions, biomechanical constraint, tensile forces between the cranial base and neurocranium, abnormalities in the cranial base, and primary pathology within the developing sutures. These have largely been supplanted by advances in genetics and sophisticated molecular research in animal models of both normal cranial suture fusion and knockout animals with craniosynostosis, resulting in improved understanding of molecular interactions in the suture complex.

Opperman et al¹⁸ and Roth et al¹⁹ have conducted landmark studies in tissue interaction. They demonstrated the integral role of dura mater in preventing synostosis, suggesting biochemical interactions rather than biomechanical forces were responsible for maintaining the suture. Molecular studies have highlighted the interconnection of transcription factors, cytokines, growth factor receptors, and extracellular matrix molecules. Most craniosynostosis syndromes result from mutations in genes encoding *FGFR1*, *FGFR2*, and *FGFR3*, in addition to the transcription factors *TWIST* and *MSX2*. Gain-of-function mutations in the *FGFR* family are associated with Crouzon, Pfeiffer, Apert, Jackson-Weiss, and Muenke syndromes.²⁰ Mutation of the FGF receptors results in increased affinity between the ligand and the receptor. The transforming growth factor- β (TGF- β) family has also been shown to have an important role in suture fusion, with increased signaling of TGF- β 1 and TGF- β 2 in multiple animal models.²¹ Bone morphogenetic protein (BMP), a member of the TGF- β family, has been cited as a source of abnormal suture formation. Warren et al²² surmised that syndromic *FGFR*-mediated craniosynostosis could be the result of abnormal downregulation of noggin (a BMP antagonist) expression. Murine studies showed that a mutation in the transcription factor *MSX2* appeared to have a dose-responsive effect on cranial suture fusion.²³ A mutation in the transcription factor *TWIST*

is responsible for Saethre-Chotzen syndrome, with in vitro studies suggesting it initiates osteoblast proliferation and differentiation.²⁴ Both MSX2 and TWIST appear to be linked to the FGF pathways. The use of transgenic mice has increased our understanding of the role of Wnt signaling in cranial suture regulation, and the use of knockouts of Axin-2 (a negative regulator of Wnt) have shown premature cranial suture fusion histologically.²⁵

Ultimately, craniosynostosis probably results from the interaction between proliferation and differentiation of osteoprogenitor cells and abnormalities in cell signaling and tissue interactions within the cranial suture.²⁶

FUNCTIONAL ISSUES

Surgeons need to determine whether patients suspected of having craniosynostosis have an isolated, single-suture event or a manifestation of an underlying syndrome. Those with single-suture, nonsyndromic craniosynostosis may have relatively straightforward issues related to possible intracranial hypertension and psychosocial concerns regarding aesthetics, whereas those with craniofacial dysostosis syndromes are some of the most complex cases for craniofacial teams to manage.

Increased Intracranial Pressure and Intracranial Anomalies

In the presence of a fused cranial suture, a rapidly growing infant brain may not have enough room for full development. This is a simplistic but useful approach to understanding and recognizing the potential for the development of increased intracranial pressure (ICP) in infants with craniosynostosis. However, in addition to craniocerebral disproportion, other factors that can be involved in the development of intracranial hypertension include abnormal venous drainage anomalies, the presence of hydrocephalus, and obstructive sleep apnea. These findings are more often seen in syndromic cases.

In classic studies, Renier et al²⁷ and Thompson et al²⁸ reported on a series of patients with craniosynostosis who underwent overnight direct ICP monitoring. They focused attention on the prevalence of intracranial hypertension in single- and multiple-suture craniosynostosis. They detected elevated ICP in up to 17% of single-suture patients and in up to 47% of multiple-suture craniosynostosis patients. The studies drew awareness to the potential detrimental effect on brain development and visual function if these problems are left untreated.

Patients diagnosed with elevated ICP can be challenging to manage. Clinical findings such as bulging fontanelles, suture diastasis and failure to thrive, headache, and vomiting may indicate intracranial hypertension. However, most children typically do not have symptoms or warning signs for a prolonged period before they are diagnosed with ICP. Radiographic findings such as a copper-beaten skull or thumbprinting on the endocranial surface are nonspecific but may corroborate funduscopic findings of papilledema (Fig. 24-6). The ventricles may be either excessively small or large, and erosions of the sella turcica may be seen. The most common objective method for diagnosing intracranial hypertension is a funduscopic examination for evidence of papilledema. Investigators at the University of Michigan²⁹ studied the effectiveness of papilledema as an indicator of raised ICP. They found that the presence of papilledema was a specific (less than 98%) indicator of elevated ICP. Sensitivity, however, was age dependent. It was 100% specific in children older than 8 years of age, but its absence in younger children was not necessarily reliable for ruling out the presence of intracranial hypertension. Given its ease of application, funduscopy continues to be a useful first step for managing all patients diagnosed with craniosynostosis. Other noninvasive methods for detecting intracranial hypertension include visual evoked potentials and optic nerve sheath ultrasound.^{30,31}

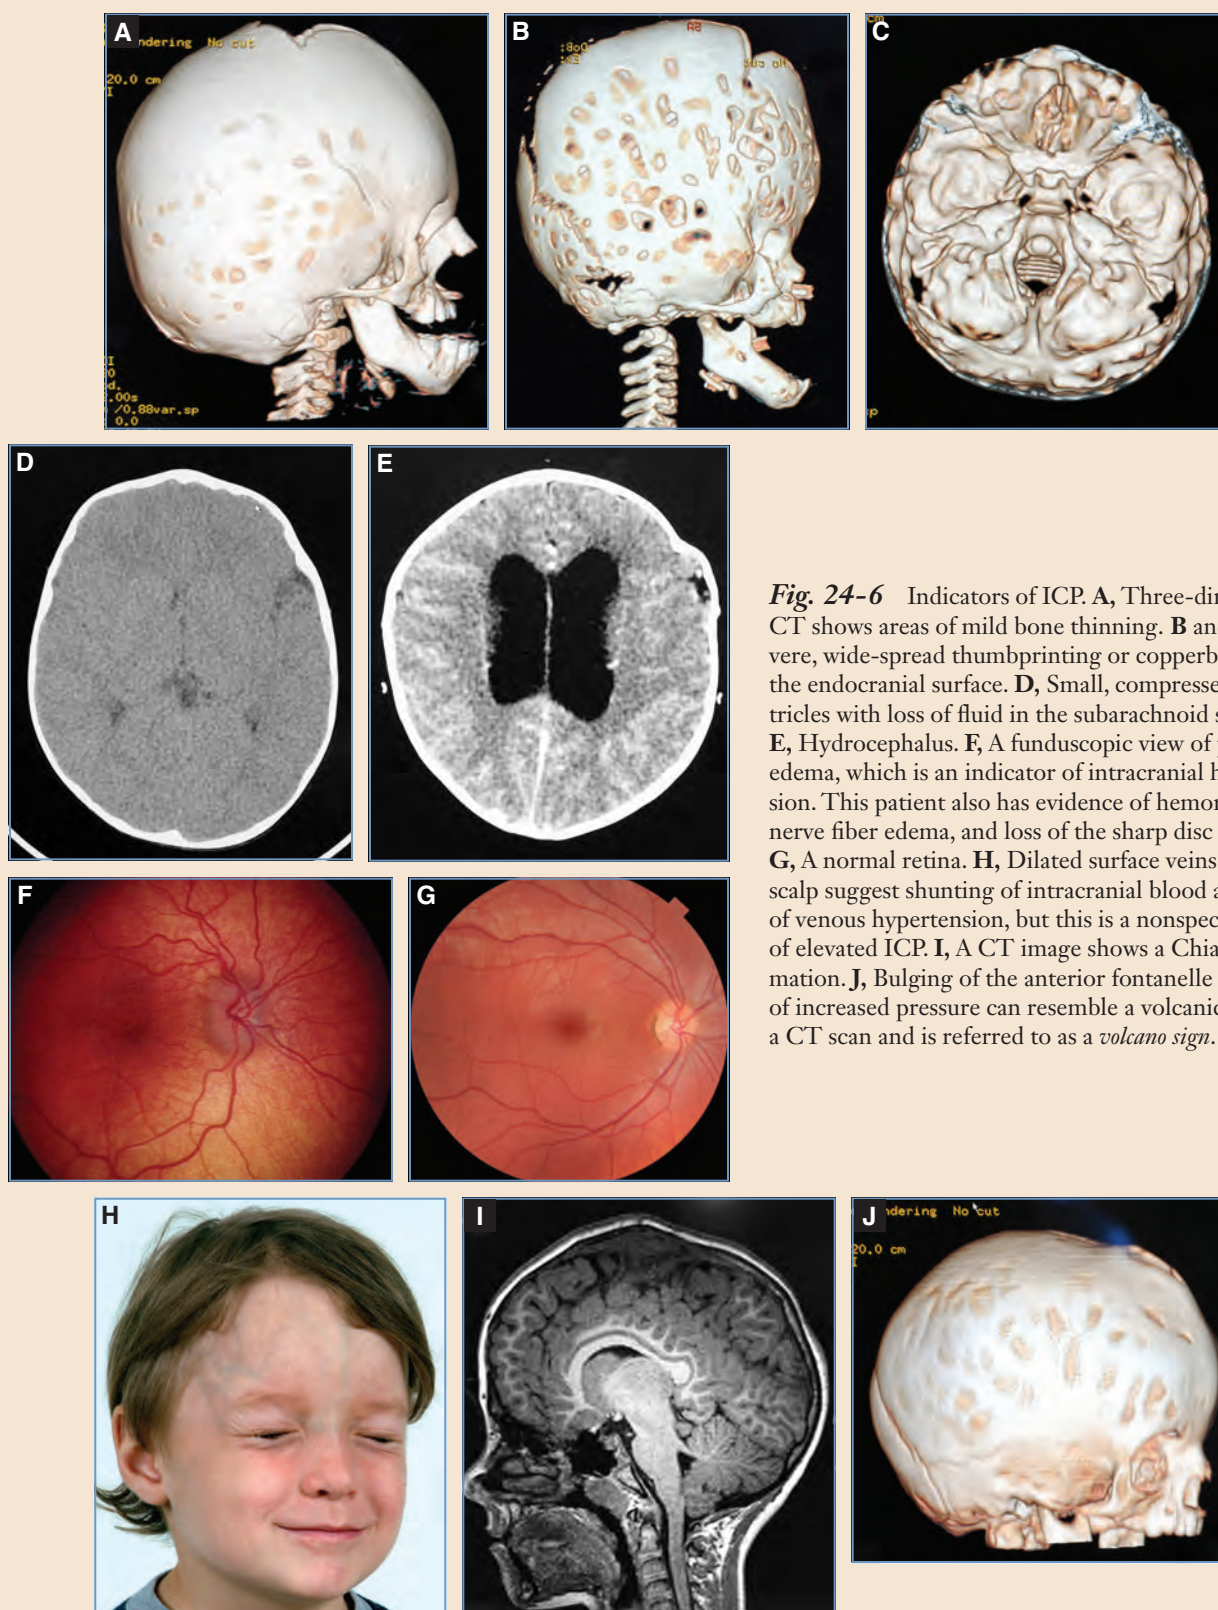

Fig. 24-6 Indicators of ICP. **A**, Three-dimensional CT shows areas of mild bone thinning. **B** and **C**, Severe, wide-spread thumbprinting or copperbeating on the endocranial surface. **D**, Small, compressed ventricles with loss of fluid in the subarachnoid space. **E**, Hydrocephalus. **F**, A fundoscopic view of papilledema, which is an indicator of intracranial hypertension. This patient also has evidence of hemorrhage, nerve fiber edema, and loss of the sharp disc margin. **G**, A normal retina. **H**, Dilated surface veins on the scalp suggest shunting of intracranial blood as a result of venous hypertension, but this is a nonspecific sign of elevated ICP. **I**, A CT image shows a Chiari malformation. **J**, Bulging of the anterior fontanelle because of increased pressure can resemble a volcanic crater in a CT scan and is referred to as a *volcano sign*.

The benchmark for assessing ICP is direct intracranial monitoring using a variety of techniques (extradural, subdural, and intraparenchymal monitors). Given its invasive nature, some centers perform this sparingly. The correlation of direct ICP measures and clinical implications is controversial. Specifically, “normal” ICP levels in nonaffected growing infants and children are not known, and adult values (higher than 20 mm Hg) may not have significance in pediatric patients. Therefore, in patients selected for direct ICP measurement, mean ICP levels with the presence of plateau waves are considered to be the most sensitive indicators of intracranial hypertension. Recent literature on the presence of ICP elevations in nonoperated, single-suture nonsyndromic craniosynostosis patients reports that up to 44% of children with sagittal and unicoronal involvement may have high ICP levels.^{32,33} However, the effect of elevated ICP on asymptomatic children is not known. Time and continued research will help to determine the clinical implications of numerically elevated pressures in clinically asymptomatic patients. ICP should be assessed in all patients with craniosynostosis.

Intracranial anomalies, hydrocephalus, and increased ICP are much more commonly seen in syndromic compared with nonsyndromic craniosynostosis patients. Intracranial hypertension has been reported in up to 50% of syndromic craniosynostosis patients, and those with Crouzon and Pfeiffer syndrome are most often affected.^{34,35} Brain anomalies in patients with syndromic craniosynostosis can be the direct result of the genetic defect or secondary to compression from craniosynostosis, raised ICP, or hydrocephalus. Brain volumes have not been found to be different in syndromic craniosynostosis patients compared with volumes in normal controls.³⁶ Venous anomalies can contribute to intracranial hypertension in children with syndromic craniosynostosis. Jugular foramen stenosis or atresia can lead to the development of collateral emissary veins, which may represent the main route for venous drainage of the cerebral venous system (Fig. 24-7). Anomalies of the venous sinuses have been identified in up to 80% of children with syndromic craniosynostosis and warrant preoperative imaging.³⁷

Hydrocephalus or ventricular dilation is present in about 40% of syndromic craniosynostosis patients.³⁸ The pathogenesis is unclear, but potential causative factors include a hypoplastic and constricted posterior fossa, venous outlet occlusion, primary brain maldevelopment, and a compensated state of increased cerebrospinal fluid outflow resistance. Crouzon and Pfeiffer syndromes are more likely to require surgical intervention in the form of a third ventriculostomy or shunt, whereas Apert syndrome is usually managed with a nonprogressive ventriculomegaly.³⁸

A Chiari malformation (herniation of the cerebellar tonsils through the foramen magnum) is frequently seen in multiple-suture and syndromic craniosynostosis patients (see Fig. 24-6, *I*). This should be documented and followed radiologically as part of the management of these patients. It is thought to result from a discrepancy between growth of the hindbrain and a small posterior fossa. The optimal management is controversial, but the association of increased ICP and Chiari malformation may necessitate a posterior cranial vault expansion and/or decompression of the foramen magnum.³⁹

Psychosocial Implications

In a single-suture nonsyndromic craniosynostosis, surgical intervention in a child with a craniofacial difference is indicated mainly to correct visual facial and cranial differences to improve craniofacial balance and quality of life. Significant evidence shows the negative psychosocial impact of a visible facial difference on behavior, social interaction, peer support, and psychiatric disease. Surgical improvement has a profound positive effect in many of these areas.^{40,41}

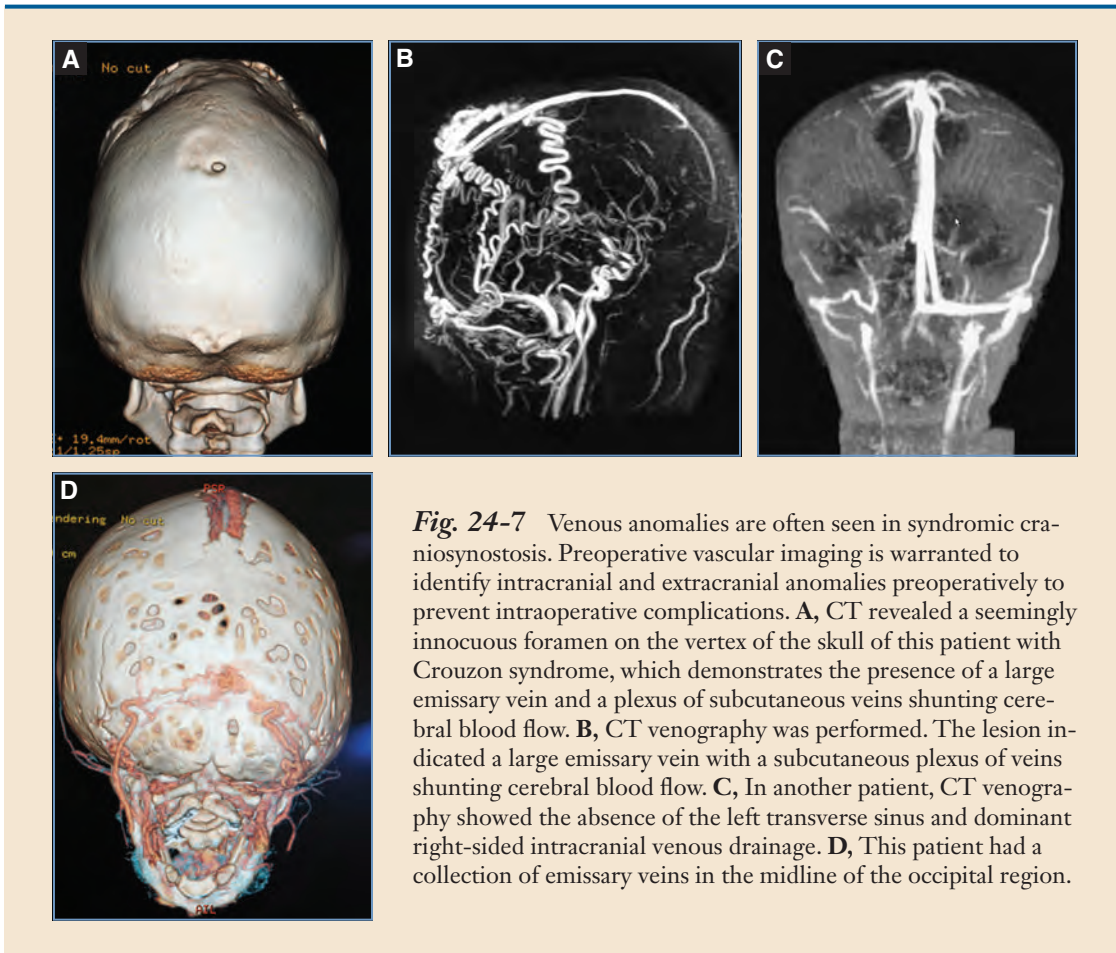

Fig. 24-7 Venous anomalies are often seen in syndromic craniosynostosis. Preoperative vascular imaging is warranted to identify intracranial and extracranial anomalies preoperatively to prevent intraoperative complications. **A**, CT revealed a seemingly innocuous foramen on the vertex of the skull of this patient with Crouzon syndrome, which demonstrates the presence of a large emissary vein and a plexus of subcutaneous veins shunting cerebral blood flow. **B**, CT venography was performed. The lesion indicated a large emissary vein with a subcutaneous plexus of veins shunting cerebral blood flow. **C**, In another patient, CT venography showed the absence of the left transverse sinus and dominant right-sided intracranial venous drainage. **D**, This patient had a collection of emissary veins in the midline of the occipital region.

Neurodevelopmental Implications

The evidence supporting an association between nonsyndromic craniosynostosis and neurodevelopmental delay is controversial. Two factors have most often been cited as causal links between single-suture craniosynostosis and impaired function: elevated ICP with hypovascularity and secondary cerebral deformation resulting from brain growth in an abnormally shaped skull.^{27,42,43} Speltz et al⁴⁴ reviewed 17 studies between 1972 and 2003, examining the neuropsychological status of children with single-suture craniosynostosis. Most children had global developmental or IQ scores within the normal range; however, 35% to 40% of assessed cases demonstrated an adverse neurodevelopmental outcome such as learning disability, language impairment, or a less precisely defined “behavioral or cognitive abnormality.” No predilection toward a specific suture was identified. In a more recent review of patients with single-suture craniosynostosis, Kapp-Simon et al⁴⁵ concluded that although global measures of intelligence and developmental status were average to low average in levels of performance, little evidence showed mental retardation or significant global deficits in cognitive function. More concerning, however, is the growing amount of evidence of school-age and older children with single-suture craniosynostosis having

deficits in neuropsychological functions, including attention and planning, processing speed, visual spatial skills, and problems in language, reading, and spelling.⁴⁵ Isolated sagittal synostosis is associated with speech and language impairment in up to 50% of affected subjects.⁴⁶

The relationship between a patient's surgical age and long-term neuropsychological outcomes in sagittal-suture craniosynostosis is equivocal. A statistically significant higher percentage of patients treated after 6 months of age had one or more reading-related learning disabilities, compared with those undergoing earlier surgery.⁴⁷ Furthermore, a comparative analysis examining the effects of two techniques related to long-term intellectual functioning showed that the type of surgical intervention for isolated sagittal synostosis may affect long-term neuropsychological outcomes. Patients undergoing early, whole-vault cranioplasty attained a higher intelligence quotient and achievement scores relative to those undergoing strip craniectomy. Surgical management with whole-vault cranioplasty performed before 6 months of age provides the most favorable long-term intellectual outcomes in patients with isolated sagittal synostosis.⁴⁸ These outcomes need to be duplicated in other centers. They show that progress needs to be made in understanding the implications of and outcomes after surgery for craniosynostosis.

Children with syndromic craniosynostosis have a higher incidence of neurodevelopmental and intellectual delay.⁴⁹ Although intracranial hypertension is often thought to be a direct cause, evidence is circumstantial. Craniocerebral disproportion may be a mechanical cause for brain anomalies such as brain distortion and cerebellar tonsillar herniation. However, it cannot be definitively linked to neurodevelopmental delay. Recent evidence demonstrates that cell adhesion molecules (L1 cell adhesion molecule) are important in the development of the white matter, requiring interactions with FGFRs.⁴⁹ *FGFR* gene mutations common to syndromic craniosynostosis may impair this interaction and lead to a variety of brain anomalies involving the white matter (for example, ventriculomegaly, callosal agenesis, agenesis of the septum pellucidum, pyramidal hypoplasia, and temporal white matter deficiencies).⁴⁹

Visual Issues

In single-suture craniosynostosis, orbital anatomy rarely affects visual function. Patients with metopic synostosis have mild hypotelorism and a pseudoesotropia resulting from the presence of epicanthal folds, but vision is usually normal. However, infants with unicoronal craniosynostosis have a high rate of amblyopia or strabismus (both 50%), but the unique shape of the plagiocephalic orbit has not proved causative.⁵⁰

The bony orbit in craniofacial dysostosis syndromes is very abnormal—often shallow and small—resulting in exorbitism and proptosis. This places the globe at risk for exposure keratitis and ulceration from lagophthalmos. Intracranial hypertension may result in irreversible optic nerve atrophy. The most common causes of visual loss are ametropia, optic atrophy, and amblyopia. Children with syndromic craniosynostosis have been found to have significant visual field deficits, as measured by kinetic visual field examination and visual evoked potentials.⁵¹ Up to 50% of children with syndromic craniosynostosis have visual impairment.⁵²

Airway Issues

Children with craniofacial dysostosis syndromes often have airway problems because of anatomic and physiologic abnormalities. They are predisposed to airway obstruction from midface retrusion caused by maxillary hypoplasia, choanal atresia, and tracheal and laryngeal anomalies. Laryngomalacia, gastroesophageal reflux, reactive airways disease, and central apnea can exacerbate these anatomic abnormalities.^{53,54} Sleep assessment has become an integral component of the workup of syndromic craniosynostosis patients. Specifically, during rapid eye movement sleep,

skeletal muscle relaxation may lead to airway obstruction with secondary increased ICP from hypercapnea-induced cerebral vasodilation. In children with preexisting compromised airways, obstructive sleep apnea will further contribute to intracranial hypertension. Airway management includes positioning measures (prone), nasopharyngeal tubes, bone distraction procedures, and in few patients, a tracheostomy. For syndromic patients who require a tracheostomy, anatomic anomalies are often identified, including a tracheal cartilaginous sleeve and a figure-of-eight trachea.⁵⁵ A thorough airway evaluation is required in infants with syndromic craniosynostosis.

PREOPERATIVE ASSESSMENT

Imaging Studies

For children with single-suture nonsyndromic craniosynostosis, a diagnosis relies heavily on the clinical assessment. Multiple-suture and syndromic craniosynostosis require a more thorough investigation, however.

Plain Radiographs

Generally, plain radiographs of the skull have limited application in the diagnosis and assessment of infants and children with craniosynostosis. The head shape, the absence of defined major sutures, elevation/sclerosis along the suture line, and evidence of thumbprinting are nonspecific findings suggestive of craniosynostosis. The presence of a harlequin-eye deformity from the vertical orientation of the orbital roof in unicoronal synostosis is one of the few signs seen on plain radiographs that is diagnostic for craniosynostosis (see Fig. 24-11). In metopic synostosis, the orbits have a trapezoidal shape that can be seen on plain films.

Computed Tomographic Scans

CT is the highest-standard modality for the radiographic evaluation of children with craniosynostosis. It is useful for definitively diagnosing craniosynostosis and for providing important information about the head shape, bony architecture, suture pattern, brain anomalies (for example, Chiari malformations, hydrocephalus, and white matter anomalies), and vascular anatomy. CT imaging and vascular anatomy assessment are necessary in syndromic craniosynostosis patients, but their application in nonsyndromic craniosynostosis cases is controversial.⁵⁶

CT in infants and children with single-suture craniosynostosis is a concern because of the negative impact of ionizing radiation exposure and because of the possibility of developing malignancy later in life. Most craniofacial surgeons agree that CT scans are not necessary for diagnosing craniosynostosis in most nonsyndromic single-suture cases, because clinical assessment is highly accurate in experienced hands.⁵⁷ Sagittal suture synostosis is an exception, because other pathology, such as prematurity and ethnic and nutritional issues, can result in a similar scaphocephalic head shape. Studies have shown that reduced exposure to radiation using low-dose protocols can produce CT images of satisfactory quality to reveal suture patency and intracranial pathology.⁵⁸ In our institution, preoperative CT scans are employed using low-dose, bone-only windows, and adhere to the “as low as reasonably achievable” principle.

Cone-beam CT is a new modality that has the same advantages of lower doses of radiation. It is widely used in dentomaxillofacial planning, with increasing application for evaluation of the craniofacial skeleton.⁵⁹

Magnetic Resonance Imaging

MRI may be useful as an adjunct, because it is a superior modality for demonstrating intracranial and brain pathology without the risk of exposure to ionizing radiation. However, infants and young children require a general anesthetic to undergo this imaging study. MRA can be useful

but may not have the same degree of resolution as CT-based studies. Prenatal MRI has been employed in the diagnosis of intrauterine craniofacial abnormalities detected by ultrasound.

Ultrasonography

High-frequency two-dimensional and three-dimensional prenatal ultrasound after 15 weeks' gestation can accurately detect suture width and patency, in addition to providing useful information about head shape, and may be used to diagnose craniosynostosis.^{60,61} Postnatal ultrasound occasionally is a useful adjunct for ruling out craniosynostosis, although it tends to be user dependent with limited application.⁶²

Diagnosis

All infants and children with a suspected diagnosis of craniosynostosis should undergo a multidisciplinary clinical assessment. Input from the following specialties is essential in creating a management plan, depending on the presence of syndromic pathology and the age of the patient: plastic surgery, neurosurgery, ophthalmology, genetics, otolaryngology, occupational therapy, social work, psychiatry, oromaxillofacial surgery, orthodontics, dentistry, and nursing. Parental and family support is a powerful adjunct through special interest groups or approved internet sites.

Establishing a diagnosis of craniosynostosis starts with an appropriate clinical assessment that includes the history of the pregnancy, a possible family history of craniosynostosis, airway and feeding issues, and the general health and well-being of the infant. The following are examined: the shape of the cranial vault, the presence of ridging, the nature of the fontanelles, the head circumference, the cranial index (length/width ratio), the size and position of the orbits, facial asymmetry, the projection of the midface, and the intraoral region. Paradoxically, examining the extremities may provide the first clue to the presence of syndromic pathology, such as the presence of complex acrocephalosyndactyly (Apert syndrome) or broad distal phalanges in the thumbs and great toes (Pfeiffer syndrome).

Single-Suture Synostosis

Sagittal Synostosis

The sagittal suture is the most-often involved suture in craniosynostosis. It affects 1 in 2500 live births and is responsible for 40% to 55% of all forms of craniosynostosis. The male/female ratio is 4:1. Familial recurrence has been described in 6% of cases.⁶³

When the sagittal suture fuses, the coronal and lambdoid sutures compensate by increasing bone deposition in the frontal and occipital bones. Meanwhile, the metopic suture compensates with symmetrical bone expansion. This compensatory growth leads to a boat-shaped cranial vault, known as *scaphocephaly*, with varying degrees of frontal and occipital bossing. The forehead is high and prominent. The AP length of the skull increases, with transverse narrowing in the biparietal and bitemporal region (Fig. 24-8). Occasionally, the midvault region has a saddle-shaped deformity. This results in a lower than normal cranial index (width/length ratio).

CT features are consistent with clinical findings for head shape. The sagittal suture may have varying degrees of partial fusion (anterior and posterior), but this does not correlate well with the severity of the deformity.

Metopic Synostosis

The metopic suture is the first suture closed, between 3 and 8 months of age, and is the only cranial suture to fuse in childhood.⁶⁴ The incidence of metopic synostosis was thought to be 1 in 15,000 but may be closer to 1 in 10,000 with newer epidemiological data. Metopic synostosis previously was considered relatively uncommon, following unilateral coronal synostosis (the sec-

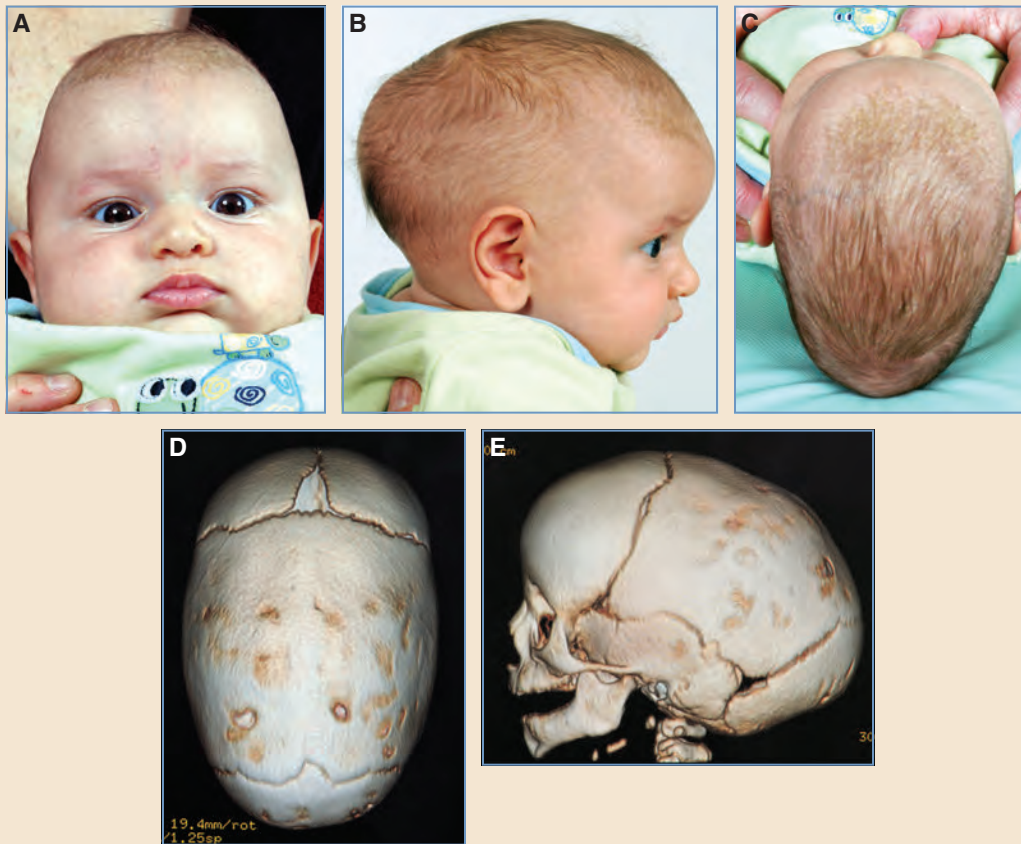

Fig. 24-8 This infant has sagittal synostosis. **A-C**, Forehead bossing, bitemporal and biparietal narrowing, prominence of the occipital region, and elongation of the head. **D** and **E**, In addition to the characteristics identified clinically, CT revealed the fusion of the sagittal suture.

and most common type) in incidence.^{65,66} However, craniofacial centers have reported that the incidence of metopic synostosis has shifted and has displaced unicoronal craniosynostosis as the second most common form seen.¹⁰ Similar to sagittal synostosis, it seems to affect more males than females, with a ratio of 3:1.⁶⁶

Premature closure of the metopic suture results in a growth restriction across the forehead and a compensatory expansion of the cranial vault posteriorly, leading to a triangle or keel-shaped forehead called *trigonocephaly* (Fig. 24-9). Additional findings include hypotelorism, pseudoesotropia, flattening of the lateral portion of the superior orbital rim, and bitemporal narrowing. Few patients will present with mild ridging along the length of the metopic suture, with no other clinical findings of trigonocephaly. This is known as *metopic ridging*. Whether this is a functional phenomenon occurring as the metopic suture normally fuses or whether it represents a form fruste of true metopic synostosis is controversial (Fig. 24-10). It is a source of concern for parents, especially when the infant presents after 8 to 10 months of age, because a CT investigation will demonstrate a fused metopic suture that can be misconstrued as a true craniosynostosis.⁶⁷ Metopic ridging rarely requires surgical attention.

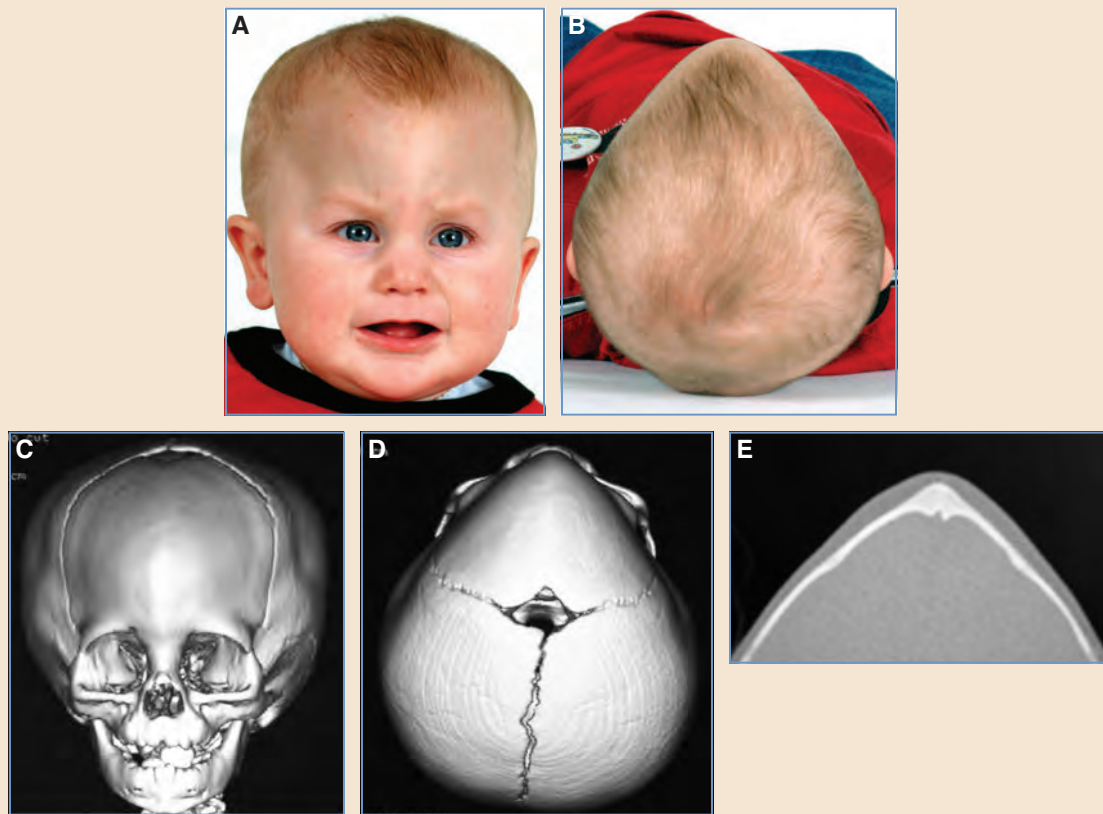

Fig. 24-9 This 8-month-old male has metopic synostosis. **A** and **B**, Hypotelorism and a midline forehead prominence were evident clinically. **C-E**, CT revealed the additional findings of a trapezoidal orbital configuration, trigonocephaly with posterior cranial vault compensatory expansion, and a small midline notch on the endocranial surface, known as an *omega sign*, often seen in metopic synostosis.

Fig. 24-10 Metopic ridging in a 10-month-old male. This may be a form fruste of metopic synostosis. Patients present with a midline ridge along the fused metopic suture but do not have the accompanying features of true metopic synostosis such as lateral orbital wall recession and hypotelorism.

More than any other single-suture craniosynostosis, trigonocephaly has been associated with syndromes such as Saethre-Chotzen, Opitz C trigonocephaly syndrome, Say-Meyer trigonocephaly syndrome, Christian syndrome, and Floating-Harbor syndrome. It has also been associated with several chromosomal anomalies such as Jacobsen syndrome.⁶⁸

CT features include a triangular shape to the head, a fused metopic suture, hypotelorism, and a characteristic trapezoidal shape to the orbits, with converging axes. One finding described to be pathognomonic of metopic synostosis is the omega sign, which is a bony groove on the endocranial surface along the length of the anterior sagittal sinus⁶⁸ (see Fig. 24-9).

Unilateral Coronal Synostosis

Unilateral coronal synostosis results in asymmetrical bossing of the forehead, which is *anterior plagiocephaly*. It was reported as the second most common type of craniosynostosis (20% to 25%), occurring in 1 in 15,000 live births; however, recent data trends suggest that metopic synostosis occurs more frequently than unilateral coronal synostosis.⁹ Unicoronal synostosis is more common in females and more common on the left side. Molecular genetic screening is recommended to determine the presence of *FGFR3* mutation associated Muenke syndrome. Visual anomalies such as strabismus and amblyopia affect up to 50% of patients with unicoronal synostosis.⁵⁰

Although unicoronal synostosis involves the fusion of only one suture, it has a characteristic bilateral deformity. Patients have forehead flattening and bulging in the temporal region on the affected side and contralateral forehead bossing from compensatory growth. The nasal root is deviated and points to the side of the synostosed suture (Fig. 24-11). Orbital asymmetry is obvious; the orbit on the affected side is larger and rounder than the smaller, beady-eyed orbit on the contralateral side.

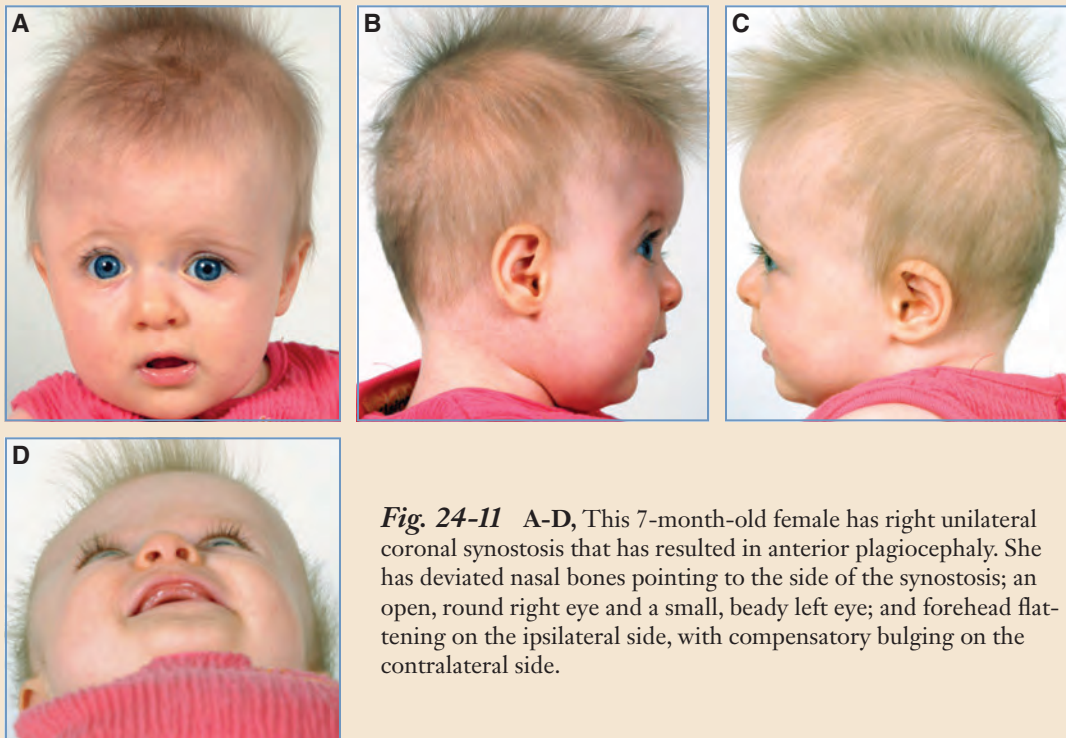

Fig. 24-11 A-D, This 7-month-old female has right unilateral coronal synostosis that has resulted in anterior plagiocephaly. She has deviated nasal bones pointing to the side of the synostosis; an open, round right eye and a small, beady left eye; and forehead flattening on the ipsilateral side, with compensatory bulging on the contralateral side.

Continued

Fig. 24-11, cont'd E-J, CT images show posterior angulation of the lateral orbital wall on the side of the fused suture and significant cranial base asymmetry. K, A plain radiograph demonstrates vertical orientation of the sphenoid wing, known as a *harlequin-eye sign*, on the side of the synostosed coronal suture.

CT findings include foreshortening of the anterior cranial fossa on the side of the synostosed suture, a harlequin-eye deformity from ventral displacement of the greater wing of the sphenoid in the orbital roof, an acute angulation between the lateral orbital wall and the zygomatic arch, and deviation of the anterior fontanelle to the side opposite the affected suture.

Bilateral Coronal Synostosis

Isolated nonsyndromic bilateral coronal synostosis is quite rare and more frequently seen in the myriad craniosynostosis syndromes. The presence of midface retrusion may be an indicator of syndromic pathology. The coronal ring consists of the paired coronal sutures and the fronto-sphenoidal and sphenothmoidal sutures along the anterior cranial base. Fusion of these cranial sutures restricts AP growth of the cranium, resulting in brachycephaly. Compensatory growth through the sagittal and squamosal sutures causes vertical elongation of the skull (turriccephaly), and often the two deformities coexist (turribrachycephaly). Bilateral temporal bulging occurs frequently, with recession of the supraorbital rim behind the anterior projection of the cornea (Fig. 24-12). CT findings include bilateral harlequin-eye deformities and severe shortening of the anterior cranial fossa. The cranial base has a transverse oval shape. Delayed onset of bilateral coronal sutures has been described as *oxycephaly*.

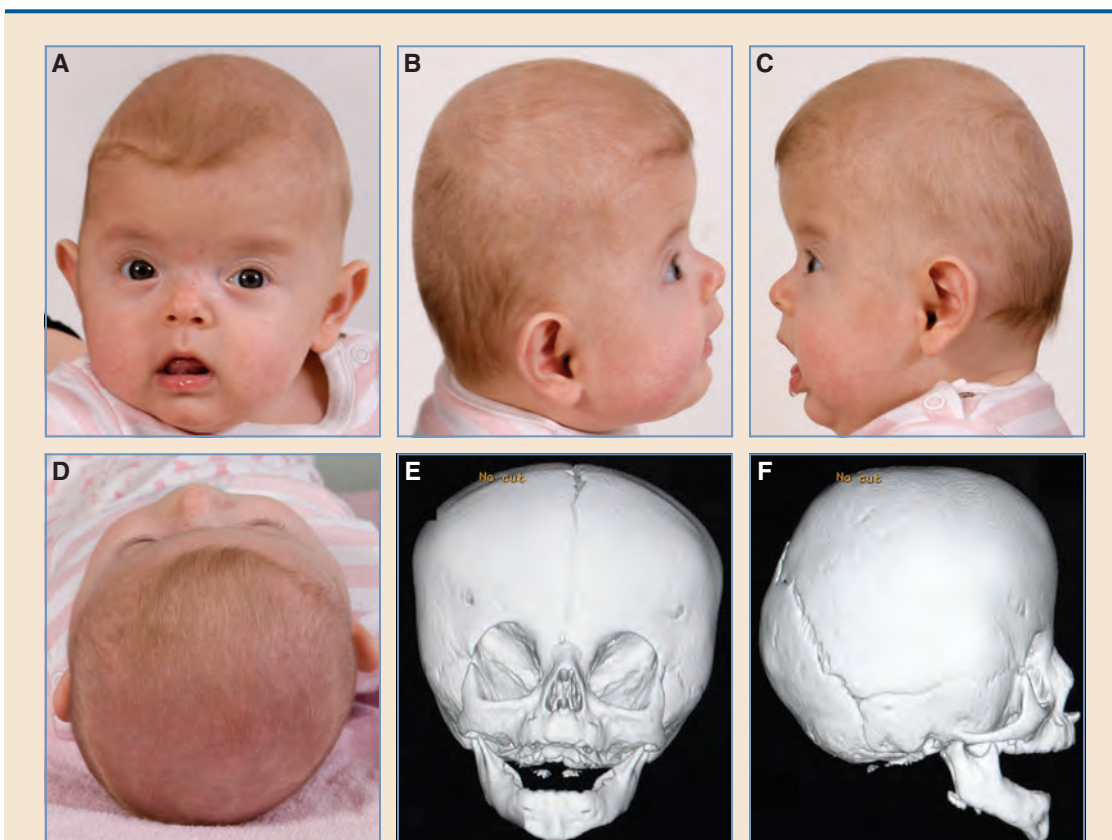

Fig. 24-12 A-D, Although bilateral coronal synostosis is usually associated with a syndrome, it can rarely occur as an isolated finding and may be distinguished from syndromic craniosynostosis by the absence of midface retrusion. Fusion of both coronal sutures in this 5-month-old girl resulted in a tall, foreshortened skull with bitemporal bulging and recession of the supraorbital rims (turribrachycephaly). E and F, CT imaging shows no evidence of midface retrusion in this nonsyndromic patient.

Lambdoid Synostosis

Of the major cranial sutures, lambdoid synostosis is the rarest form of premature suture fusion, comprising 1% to 5% of all craniosynostoses and occurring in 1 in 100,000 live births.^{69,70} It is difficult to diagnose clinically but is classically characterized by ipsilateral occipital flattening, posteroinferior displacement of the ipsilateral ear, bossing of the ipsilateral mastoid, and ipsilateral decreased height of the cranial vertex (Fig. 24-13). These findings combine to form a trapezoidal skull shape when viewed from above. From behind, cranial base canting and inferior displacement of the ipsilateral ear are seen.

Lambdoid synostosis needs to be distinguished from deformational plagiocephaly (plagiocephaly without synostosis, known as *positional plagiocephaly*), which has become exceptionally common because of prone sleeping practices designed to reduce the incidence of sudden infant death syndrome.⁶⁹ Deformational plagiocephaly has a characteristic parallelogram shape when viewed from above (Fig. 24-14 and Table 24-3). Specifically, patients have occipital flattening associated with anterior positioning of the ipsilateral ear and forehead. The ear position is equal

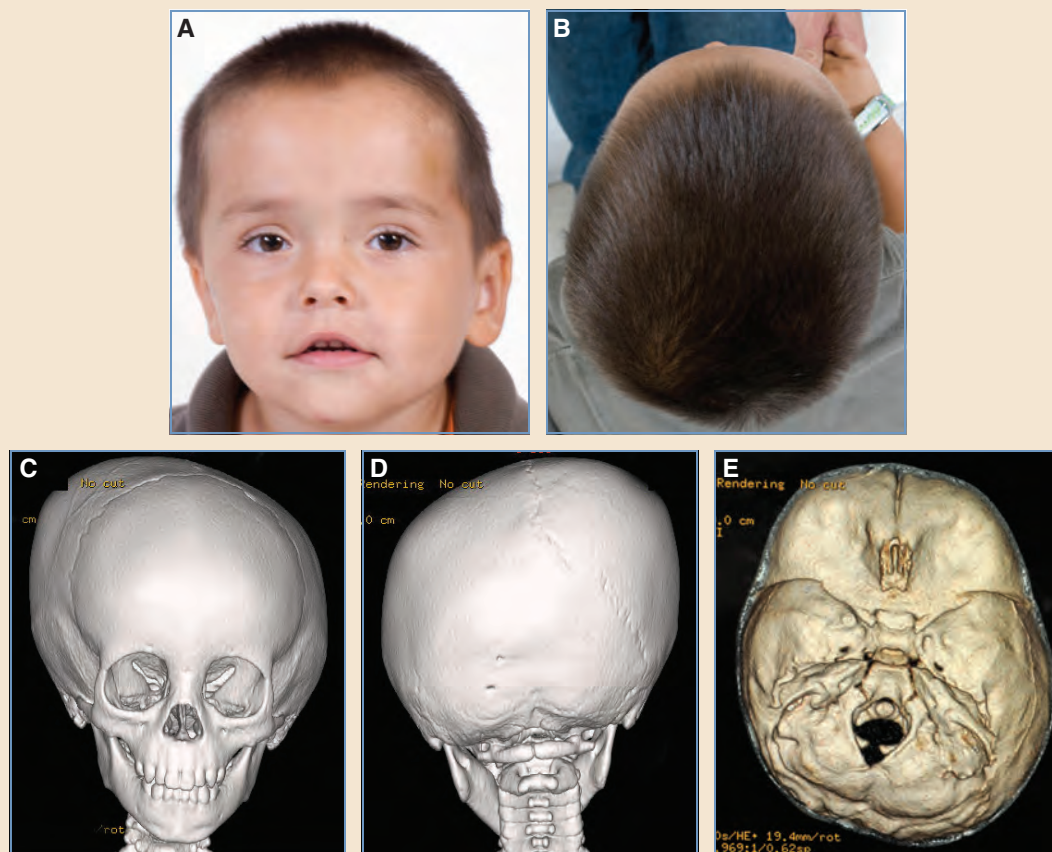

Fig. 24-13 A and B, Left lambdoid synostosis in a young boy. There is asymmetry present in the frontal view and a trapezoidal shape to his head from above. C-E, CTs demonstrate left lambdoid suture fusion with a compensatory vertical prominence on the opposite side of the skull; canting of the skull base on the posterior view with a mastoid bulge on the side of the synostosed suture; and marked asymmetry and volumetric differences between the two sides of the posterior fossa on the cranial base view.

when viewed from behind no matter how severe the deformity. The incidence of deformational plagiocephaly is very common, affecting up to 1 in 7 infants. Many of the babies are born with round heads, whereas those with lambdoid synostosis have the deformity at birth.⁷⁰

CT findings demonstrate the deformities described previously and significant asymmetry in the cranial base (see Fig. 24-13).

Fig. 24-14 Differentiation of deformational plagiocephaly and lambdoid synostosis.

Table 24-3 Comparison of Plagiocephaly and Lambdoid Synostosis

	Positional Plagiocephaly	Lambdoid Synostosis
Age at onset	2+ weeks after birth	Present at birth
Bird's-eye view of head shape	Parallelogram	Trapezoidal
Forehead on the affected side	Anteriorly displaced	Symmetrical or retruded
Ear position on the affected side	Anteriorly displaced	Posteriorly displaced
Skull base viewed from behind	Ears level	Ears uneven (the affected side is lower)
Natural history	Improvement*	Worsens during the first year of life, then stabilizes
Incidence	Very common	Very rare (from 1 in 100,000 to 1 in 130,000) ⁷⁰

*Assuming the patient has no torticollis or significant developmental delay.

Multiple-Suture Synostosis

Approximately 5% of all cases of craniosynostosis involve multiple sutures.⁷¹ Almost any pattern of multiple-suture synostosis can exist, but involvement of both lambdoid and sagittal sutures has been formally recognized as the *Mercedes-Benz* pattern of craniosynostosis, referring to the three-pointed star emblem of the automobile company.^{72,73} Patients with multiple-suture involvement have complex problems and often have associated Chiari malformations and signs of intracranial hypertension.

Minor Suture Variants

Although fusion of the minor sutures is less common, it can alter the skull shape and make diagnosis challenging. Isolated frontosphenoidal synostosis may mimic unicoronal synostosis and produce anterior plagiocephaly.⁷⁴ Frontozygomatic suture synostosis has been reported.^{75,76} Distinguishing these variants will rely on CT imaging.

Syndromic Craniosynostosis

A syndrome can be considered a constellation of signs and symptoms that, together, characterize a clinical condition. Craniosynostosis has been detected in more than 180 different syndromes, and the number continues to increase as sophisticated molecular genetic analyses help to identify new syndromes.⁷¹ Identifying syndromic craniosynostosis requires a combination of clinical, radiologic, and molecular genetic assessment. Phenotype alone may not be a reliable indicator of the type of syndrome, because several may share similar craniofacial suture involvement, often including the coronal ring (see Fig. 24-12). The main craniosynostosis syndromes are discussed in the following sections.

Apert Syndrome

Apert syndrome was first described in 1894 and is characterized by bilateral coronal craniosynostosis, midface retrusion, exorbitism, complex symmetrical acrocephalosyndactyly, radiohumeral

Fig. 24-15 A and B, This 11-month-old female has Apert syndrome. She has hypertelorism without severe exorbitism, turribrachycephaly from bicoronal synostosis, midface retrusion, and a parrot-beak nasal deformity.

fusion, and variable degrees of neurodevelopmental delay.⁷⁷ The nose is short and wide with a bulbous tip, and the anterior facial height is reduced (Fig. 24-15). The incidence is 1 in 70,000.⁷⁸ Apert syndrome is transmitted in an autosomal dominant fashion, although the most cases result from a spontaneous mutation in *FGFR2*. It accounts for approximately 4% of all cases of craniosynostosis.⁷⁸ The male/female ratio is equal.

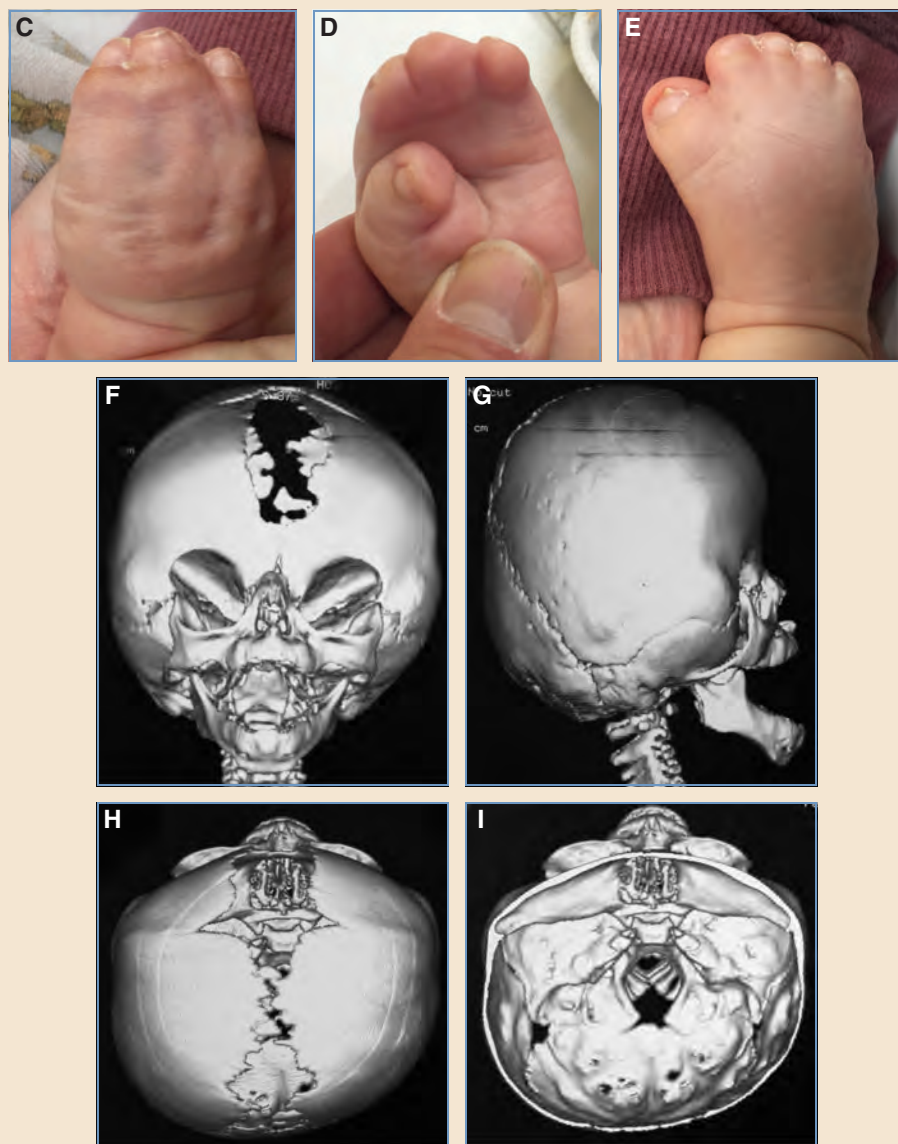

Fig. 24-15, cont'd C-E, The diagnosis is established by examining the extremities, which have complex acrocephalosyndactyly. F-I, CT images demonstrate bicoronal synostosis; a large, confluent anterior fontanelle; bitemporal bulging; divergent orbital axes; and maxillary retrusion.

Crouzon Syndrome

Crouzon first described this syndrome in 1912.⁷⁹ Clinical characteristics include bilateral coronal craniosynostosis, exorbitism with hypertelorism, maxillary hypoplasia with relative mandibular prognathism, and normal intelligence (Fig. 24-16). Delayed-onset pansynostosis with intracranial hypertension has been described in a subset of Crouzon syndrome patients and should be carefully monitored. The incidence is 1 in 65,000 live births, and the syndrome is inherited in an autosomal dominant pattern with variable penetration.⁷¹ It results from a mutation in *FGFR2*. Parental involvement is typically seen. A variant of Crouzon syndrome involves acanthosis nigricans and is associated with *FGFR3* mutations. Generally, craniofacial morphology is less severe than in Apert syndrome.⁸⁰

Fig. 24-16 A and B, This 8-year-old boy has Crouzon syndrome, with severe exorbitism, midface retrusion, and mild turribrachycephaly from bicoronal synostosis. C and D, CT images reveal evidence of previous cranioorbital reshaping.

Pfeiffer Syndrome

Pfeiffer syndrome presents with bicoronal synostosis and may resemble Crouzon syndrome because of the presence of proptosis, hypertelorism, and maxillary hypoplasia (Fig. 24-17). It is distinguished by extremity anomalies, namely broad great toes and thumbs, partial syndactyly, and brachymesophalangy.⁸¹ The incidence is 1 in 100,000 live births and may be transmitted in an autosomal dominant fashion. Molecular genetic analyses have identified a sporadic mutation in *FGFR1* or *FGFR2*. A new classification system stratifies patients according to functional assessment of respiratory, ocular, otologic, and neurologic status.⁸²

Fig. 24-17 A and B, This girl with Pfeiffer syndrome has severe exorbitism and midface retrusion. She has a tracheostomy for airway protection. C-E, CT shows bicoronal synostosis with midface retrusion and shallow orbits. F and G, Phenotypically, it is hard to differentiate Crouzon syndrome and Pfeiffer syndrome on the basis of facial dysmorphism. An examination of the extremities may reveal wide distal thumbs and great toes and simple syndactyly in patients with Pfeiffer syndrome.

Saethre-Chotzen Syndrome

Saethre-Chotzen syndrome is characterized by unilateral or bilateral coronal craniosynostosis, a low hairline, ptosis of the upper lids, syndactyly of the second and third digits, ear anomalies (prominent superior crus), and normal intelligence⁸³ (Fig. 24-18). The incidence is 1 in 25,000 to 1 in 50,000 births, and it is inherited in an autosomal dominant fashion and results from a mutation in *TWIST1*.⁸³ In contradistinction to other cases of syndromic craniosynostosis, midface retrusion is unusual.

Fig. 24-18 A and B, This 13-year-old boy has Saethre-Chotzen syndrome, characterized by mild upper lid ptosis, turribrachycephaly from bicoronal synostosis, and supraorbital rim retrusion. C, His ears have characteristic prominent superior crura. D, There is evidence of bilateral simple syndactyly of the fingers. E, A lateral cephalometric radiograph shows a tall, retruded forehead; fusion of both coronal sutures; and a class I dental and skeletal relationship.

Muenke Syndrome

Patients with Muenke syndrome have a specific *FGFR3* pathogenic variant that results in the protein change Pro250Arg. The reported incidence is 1 in 30,000 live births.⁸⁴ The phenotype is highly variable and may include unilateral or bilateral coronal craniosynostosis, brachydactyly, carpal and tarsal fusions, sensorineural hearing loss, a Klippel-Feil cervical anomaly, and variable degrees of mental impairment^{84,85} (Fig. 24-19). The incidence is variable. Muenke syndrome affects up to 20% of coronal synostosis patients and is inherited in an autosomal dominant manner. Females with the Pro250Arg mutation are significantly more likely to have craniosynostosis than males.⁸⁶

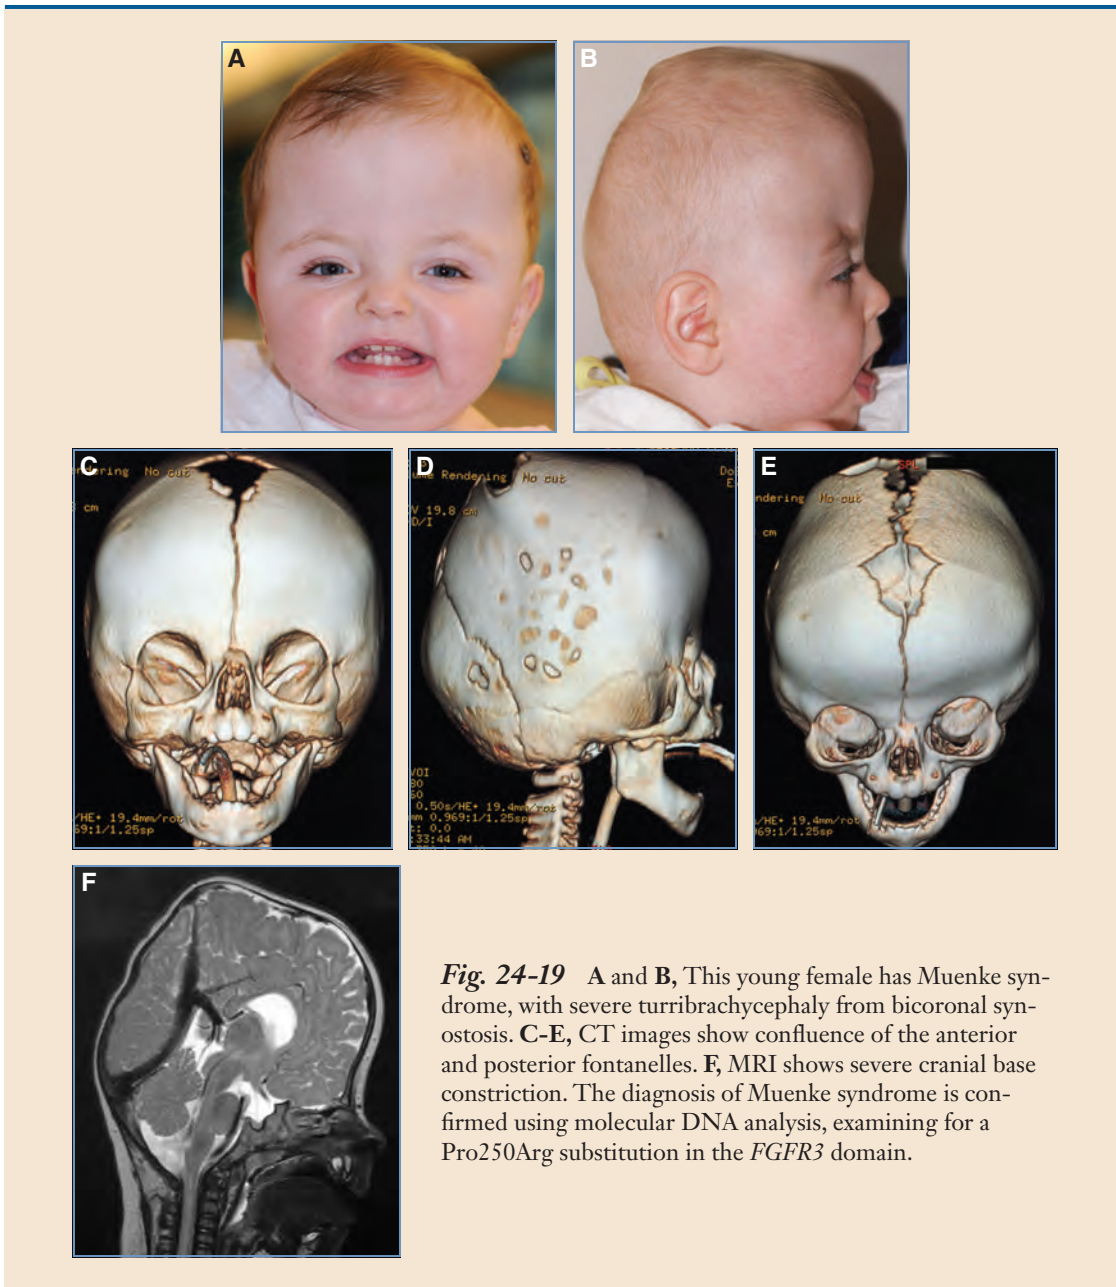

Fig. 24-19 A and B, This young female has Muenke syndrome, with severe turribrachycephaly from bicoronal synostosis. C-E, CT images show confluence of the anterior and posterior fontanelles. F, MRI shows severe cranial base constriction. The diagnosis of Muenke syndrome is confirmed using molecular DNA analysis, examining for a Pro250Arg substitution in the *FGFR3* domain.

Kleeblattschädel

Kleeblattschädel is a German word for *cloverleaf* and describes the most severe form of multiple-suture craniosynostosis. It is a clinical finding and not a diagnosis (Fig. 24-20). Synostosis usually involves the lambdoid, coronal, and skull base sutures; the sagittal and temporal squamosal sutures fuse in a delayed fashion. The degree of severity will vary according to the involvement of different sutures. With growth, compensatory bulging results in the classic trilobar or three-part cloverleaf shape of the cranial vault. The cause is heterogeneous. Kleeblattschädel often represents a manifestation of Pfeiffer or Crouzon syndrome. Intracranial pathology such as Chiari malformation and hydrocephalus is common. Significant morbidity and mortality are common.⁸⁷

Fig. 24-20 A and B, This infant has Crouzon syndrome, with severe exorbitism, a bulging forehead, and bilateral temporal bulges. C-E, CT scans show severe thumbprinting, bicoronal synostosis with temporal squamosal and metopic involvement, and midface retrusion.

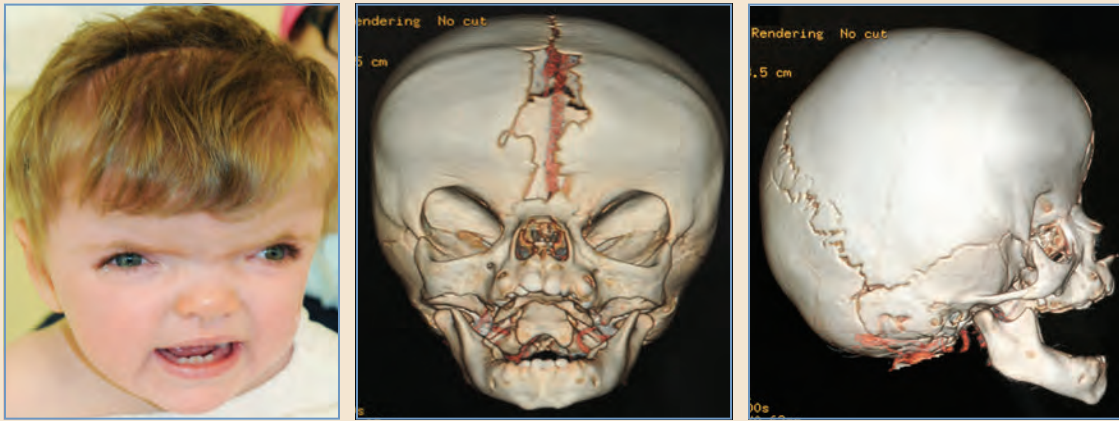

Fig. 24-21 This 8-month-old female has craniofrontonasal dysplasia, with turribrachycephaly and hypertelorism. It should be suspected in patients who have unicoronal or bicoronal synostosis and hypertelorism without evidence of midface retrusion.

Craniofrontonasal Dysplasia

Craniofrontonasal dysplasia is a rare, X-linked craniosynostosis syndrome caused by a mutation in the *EFNB1* gene.⁸⁸ It has a variable phenotypic expression, but females are more often and more severely affected than males. It commonly involves the coronal suture or sutures and is associated with orbital hypertelorism; a bifid nose; dry, frizzy hair; longitudinal ridging of the nails; and anomalies of the upper extremity (Fig. 24-21). It may be clinically distinguished from frontonasal dysplasia (which is a clefting sequence) by the presence of craniosynostosis.⁸⁸

SURGICAL APPROACHES TO CRANIOSYNOSTOSIS

Surgical correction of single-suture synostosis usually requires a single, major procedure in the first year of life. Most patients undergo significant improvement but are followed closely for the possibility of relapse and the need for a touch-up surgery. On the contrary, syndromic craniosynostosis requires a series of staged, age-dependent procedures performed from infancy to skeletal maturity. Relapse rates in patients with syndromic craniosynostosis are high, and the outcome is based more on the biology of the underlying condition than on the surgical technique. Protocols vary from center to center but essentially focus on airway compromise, cranial dysmorphism, and ocular and intracranial pathology in the first few years of life. The makeup of the surgical craniofacial team varies from center to center, but key members are from the following departments: pediatric anesthesia, nursing, plastic and reconstructive surgery, neurosurgery, oromaxillofacial surgery, otolaryngology–head and neck surgery, critical care, and ophthalmology.

Craniosynostosis surgery is designed to address cranial dysmorphology, craniocerebral disproportion, orbital position, and intracranial hypertension. The myriad techniques that have been described can be classified as static or dynamic and compressive or decompressive. Craniofacial units disagree about which is the best technique. Postoperative care is provided in critical care or high-acuity observation rooms.

History of Surgical Treatment

The surgical treatment of craniosynostosis has a long history that started in the late nineteenth century. Almost simultaneously in the 1890s, a French surgeon, Lannelongue⁸⁹ and an American, Lane,⁹⁰ described linear craniectomies and removal of the pathologic suture in an attempt to correct mental “imbecility” from premature sutural closure and microcephaly.

Despite best intentions, the mortality rate was almost 50% in the first 33 children treated in this manner. Jacobi,⁹¹ thought to be the father of American pediatrics, condemned the procedure in 1894. Interest in surgery for craniosynostosis was minimal for almost the next three decades.

Surgical techniques and anesthesia improved, and in the 1920s Faber and Towne⁹² pioneered the concept of prophylactic linear strip synostectomy. They reported excellent preservation of function with minimal morbidity and mortality using this procedure, which they recommended for infants 1 to 3 months of age.

The concept of unlocking the growth potential of the craniofacial skeleton by releasing the fused suture in the growing skull continues to resonate in the modern-day philosophy of craniosynostosis surgery. However, surgeons continued to be vexed by postoperative, rapid reossification and relapse of the deformity. This led to numerous strategies to prevent bone ingrowth, including the use of caustic solutions on the dura and the placement of silastic and metal interpositional devices.

In 1967 Tessier⁹³ introduced new techniques and principles of cranial vault remodeling, bone grafting, and stabilization. These operations were significantly more radical in their scope and correction. Tessier showed that the craniofacial skeleton could be osteotomized and reassembled, and with stabilization of the bone, this technique would lead to predictable and reproducible outcomes. He achieved these results before the advent of sophisticated CT imaging techniques, making his intuitive skills and clinical insights even more remarkable. These principles and techniques are the cornerstone of current management philosophies for craniosynostosis repair. Many of Tessier's fellows and disciples have refined his original techniques. Subsequently, sophisticated anesthesia monitoring systems, blood conservation techniques, and small titanium and bioresorbable bone fixation and bone distraction systems affected craniofacial surgery in major ways, improving safety and outcomes.

Anterior Cranioorbital Reshaping With Frontoorbital Advancement

Indications

- Anterior plagiocephaly from unicoronal synostosis or minor suture variant
- Brachycephaly from bicoronal synostosis
- Trigonocephaly from metopic synostosis
- Supraorbital rim recession or asymmetry

Procedure

Anterior cranioorbital reshaping and frontoorbital advancement is a powerful tool in craniofacial surgeons' armamentarium for correcting congenital deformities of the face and skull. This procedure removes and reshapes the bones of the forehead, supraorbital rims, and often, the temporal bone. The timing of surgery varies by center. However, for single-suture nonsyndromic synostosis, surgery usually is performed when patients are 8 to 12 months of age, when the bone is thick enough to be stabilized using plate fixation and the infant is able to withstand the rigors of anesthesia, complex surgery, and blood loss. Another advantage of surgery at this age is the reossification of bone defects that results from expansion of the craniofacial skeleton. This opportunity is lost after approximately 14 to 18 months of age as the dura loses its osteogenic potential.

Access is obtained through a bicoronal incision with subperiosteal exposure of the frontal and orbital regions. After a bifrontal craniotomy, the supraorbital rim (bandeau) is removed, reshaped, and positioned accordingly. The bone segments are fixated using bioresorbable fixation designed to resorb over a 12- to 18-month period. Alternatively, wire or suture fixation is often employed. The use of titanium plate fixation is discouraged, because passive intracranial migration occurs as the cranial vault continues to grow and may be problematic for additional surgery or trauma. The use of age-matched surgical templates has significantly improved craniofacial form and reduced surgical time.⁹⁴ Forehead reconstruction is performed according to the surgeon's aesthetic judgment. Some centers advocate forehead overcorrection to accommodate growth and relapse.

Delaying anterior cranial vault remodeling and frontoorbital advancement as long as possible has the lowest risk of relapse, particularly in syndromic craniosynostosis patients.⁹⁵ Surgical correction of the posterior vault when patients are young has been advocated, because it provides adequate volume for the growing brain and delays frontal and midface surgery until the bone is more mature (Fig. 24-22).

Fig. 24-22 A and B, This 7-month-old girl had metopic synostosis and underwent an anterior cranial vault reconstruction with bilateral frontoorbital advancement.

Continued

Fig. 24-22, cont'd C-H, Preoperative CT images.

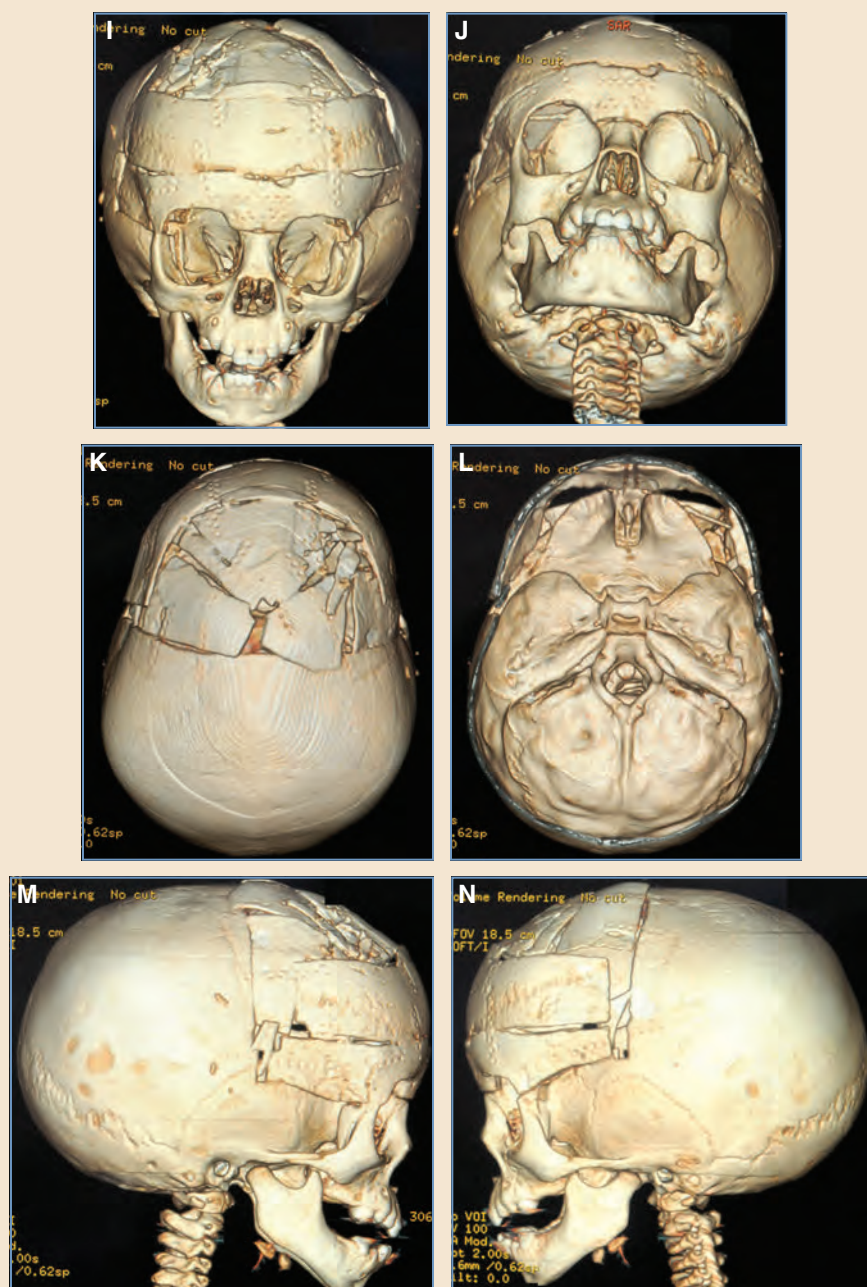

Fig. 24-22, cont'd I-N, Immediately postoperative CT images. The extent of surgery depends on the craniofacial deformity. This procedure involved removing the supraorbital rim and temporal attachment (bandeau) with subsequent reshaping. A symmetrical orbital aperture was created with a combination of contouring and reshaping maneuvers.

Posterior Cranial Vault Reshaping

Indications

- Posterior plagiocephaly from lambdoid synostosis or a minor suture variant
- Turribrachycephaly from bicoronal synostosis
- Posterior fossa constriction

Procedure

Reshaping of the posterior cranial vault addresses deformities involving the posterior parietal and occipital regions that usually result from lambdoid synostosis or from the management of turribrachycephaly. Posterior cranial vault reshaping is not as commonly performed as anterior cranial vault reshaping and carries more risks because of the presence of the venous sinuses (the confluence of the sagittal and transverse sinuses, the torcula) and the mastoid air cells and because of the prone position of the patient, usually required for access. However, expansion and reshaping of the posterior cranial vault has become an area of first focus in the management of craniocerebral disproportion in syndromic craniosynostosis, in part because posterior expansion results in proportionately more intracranial volume (35%) compared with anterior frontal advancement (12% to 18%).⁹⁶ Furthermore, it may allow a delay in frontofacial surgery in syndromic cases, thereby helping to minimize relapse and the need for a repeat surgery. Generally,

posterior cranial vault reshaping should be performed in patients 4 to 6 months of age or older, when bone is thick enough to withstand the application of fixation plates or distraction devices.

Techniques for posterior cranial expansion include a traditional craniotomy disassembly and reassembly cranioplasty (Fig. 24-23), posterior cranial vault distraction, and the use of springs.⁹⁷⁻¹⁰⁰ Cranioplasty techniques involve the use of bioresorbable plate fixation with reshaping and expansion of the cranial vault to maintain appropriate cranial form. This is an invasive technique and can be complicated by the presence of large, bony spicules on the endocranial surface that make bone removal hazardous.

Posterior cranial vault distraction has become a favored approach to posterior cranial vault expansion, because it is less invasive and allows titration of the degree of expansion and adjustment. It is a useful first-stage treatment for turricephaly associated with syndromic craniosynostosis. The procedure involves a linear posterior craniectomy, followed by the application of small bone distractors. It does not incur the same risks of dural tears and sinus breach, because the bone is not removed (Fig. 24-24). The posterior cranial vault is slowly distracted at a rate of 1 mm per day to gradually expand the intracranial volume. This technique may also be used

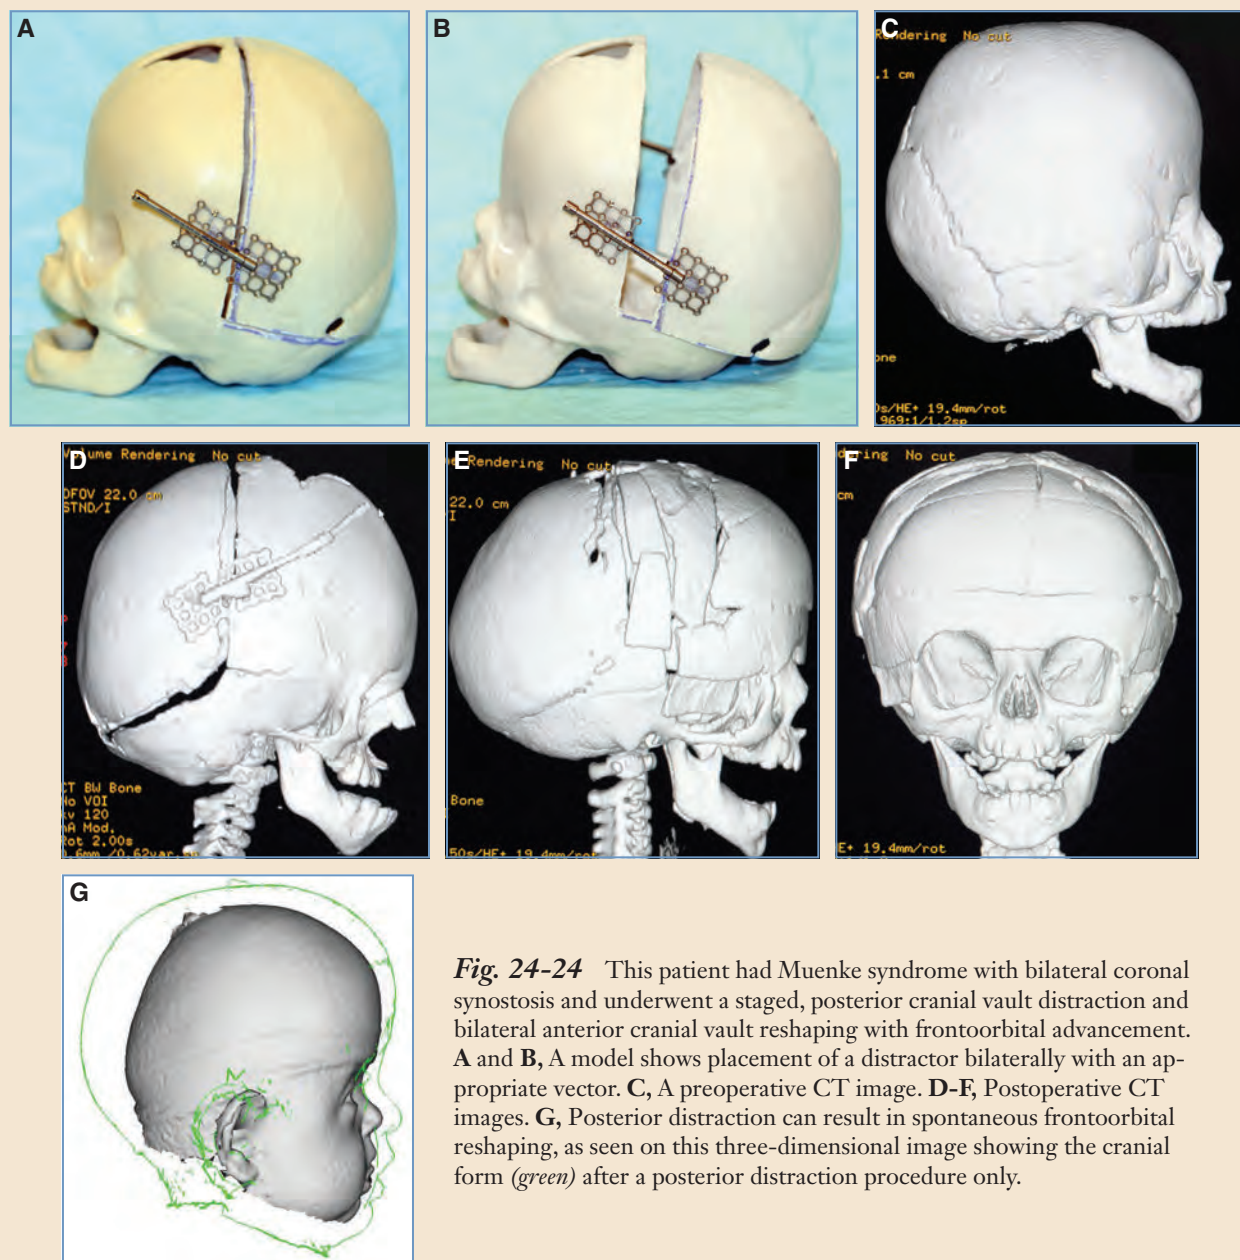

Fig. 24-24 This patient had Muenke syndrome with bilateral coronal synostosis and underwent a staged, posterior cranial vault distraction and bilateral anterior cranial vault reshaping with frontoorbital advancement. **A** and **B**, A model shows placement of a distractor bilaterally with an appropriate vector. **C**, A preoperative CT image. **D-F**, Postoperative CT images. **G**, Posterior distraction can result in spontaneous frontoorbital reshaping, as seen on this three-dimensional image showing the cranial form (green) after a posterior distraction procedure only.

to correct turriccephaly by placement of the distractors in a downward vector. Disadvantages of distraction include the cost of the distractor devices, the inability to change the vector, and the need for a second procedure to remove the devices. Posterior cranial vault distraction has led to improvement in patients with Chiari malformation and may be a useful alternative to posterior fossa decompression in selected cases.¹⁰¹

Lauritzen and colleagues^{98,99} applied springs to the craniofacial skeleton as early as 1998. The spring was made of a metallic wire that was bent and placed across an osteotomy or open suture and anchored through holes in the calvarium or at the edges of the osteotomy. The spring separated the bony fragments until its inherent prebent shape was achieved or until it reached equilibrium with the surrounding tissue forces. The advantages of the spring were the relative ease of its application, the prevention of significant dissection and multiple osteotomies, and complete soft tissue coverage, which was not possible with distractors. The major disadvantages were the lack of control of the vectors and force applied, the need for a second surgery to remove the spring, and the possible associated complications, including dislodgement, skin penetration, and pressure sores.⁹⁹

Once intracranial volume is effectively expanded by posterior vault reshaping, the frontal region is corrected in a later stage, when skeletal maturity will decrease the risk of relapse (see Fig. 24-24).

Strip Craniectomy Techniques

Indications

- Scaphocephaly from sagittal synostosis in infants younger than 6 months of age
- Multiple-suture syndromic craniosynostosis

Procedure

Historically, removing a fused suture was thought to be the logical approach to managing the calvarial deformity of craniosynostosis in unlocking the growth potential of the skull. However, the standard method of a simple synostectomy of the involved suture was not always reliable for managing patients with scaphocephaly. More extensive craniectomy techniques developed in which additional bone was removed to allow normalization of the cranial vault. Dissatisfied with the results of these procedures, Jane and colleagues^{102,103} developed the pi procedure, which involved a strip craniectomy in the shape of the Greek letter π , followed by compression of the skull in an AP direction for side-to-side expansion.

Multiple variations on the pi procedure were developed, suggesting that this technique was not a panacea for all conditions. In 1991 Marsh et al¹⁰⁴ eloquently explained that with age, the ability of the bone to remodel under the influence of the growing brain diminishes. More extensive cranioplasty techniques were advocated in lieu of strip craniectomy techniques to adequately improve cranial dysmorphism from craniosynostosis.¹⁰⁴

This changed, however, with the advent of minimally invasive surgery techniques in the 1990s. In 1998 Jimenez and Barone¹⁰⁵ described the placement of an endoscope through small incisions to perform strip craniectomies safely in infants younger than 6 months of age. Rapid brain growth and thin bone allowed normalization of the cranial vault but required a powerful adjunct in the form of an external molding helmet to be worn for 4 to 12 months postoperatively. This technique has produced acceptable improvements in cranial dysmorphism and has been reproduced at multiple centers.¹⁰⁶

Currently, strip craniectomy techniques as an open or endoscopic-assisted approach are commonly performed. They have shown that improvement in craniofacial form is possible by

taking advantage of Moss' functional matrix theory.⁴ A variety of techniques are advocated (Fig. 24-25). Strip craniectomies are still performed in some units as a first-line treatment for managing elevated ICP in syndromic, multiple-suture synostosis cases in very young infants (younger than 3 months of age). This is temporizing at best because of rapid reossification, but it may buy time before the definitive surgery.

Fig. 24-25 A and B, This 5-month-old boy had scaphocephaly as a result of sagittal synostosis. He underwent an extended strip craniectomy. C-H, Preoperative CT images.

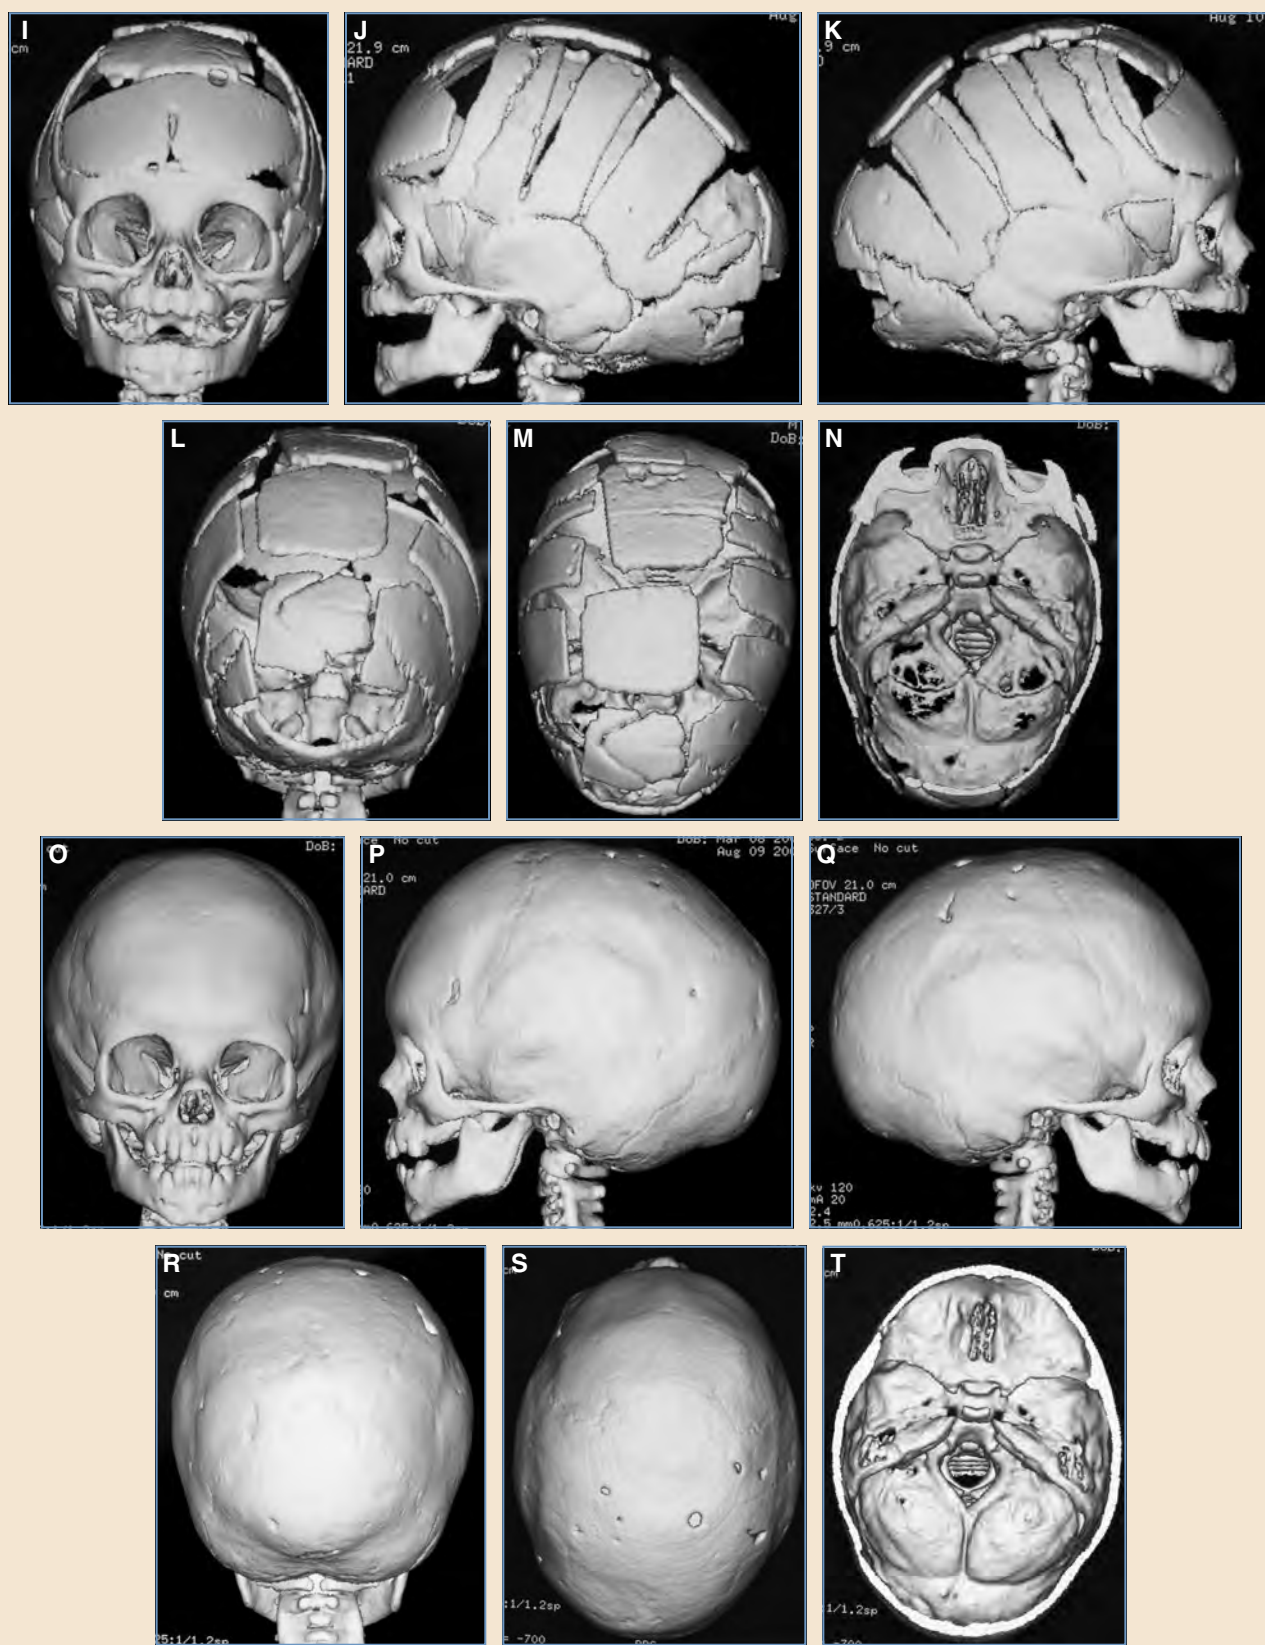

Fig. 24-25, cont'd I-N, Immediately postoperative CT images. O-T, One year postoperatively, his cranial shape has normalized.

Total Cranial Vault Reshaping

Indications

- Scaphocephaly from sagittal synostosis in infants 6 months of age and older
- Turribrachycephaly from bicoronal synostosis
- Multiple-suture synostosis

Procedure

Reshaping of the entire cranial vault is usually performed to correct cranial vault dysmorphism and craniocerebral disproportion associated with sagittal or multiple-suture syndromic cranio-synostosis. It is performed as a single or a staged procedure. Total cranial vault reshaping consists of a disassembly-reassembly cranioplasty technique using some form of fixation to maintain the cranial shape. The procedure is indicated for scaphocephaly correction in infants older than 6 months of age. Strip craniectomy techniques do not have the same degree of efficacy once the bone has thickened and brain growth starts to diminish. Ideally, if a frontoorbital bandeau is selected, it should be completed before the development of the frontal sinus to reduce the risk of contamination and infection.

For a total cranial vault reshaping, the patient is placed in a prone position for adequate access to the skull. However, this position makes airway management potentially more problematic and necessitates turning the patient intraoperatively (Fig. 24-26). The sphinx position allows access to the front and back of the cranial vault but increases the risk of air embolus and venous drainage problems, because the neck vessels are kinked with neck hyperextension.

Many of the techniques available for correcting skull deformities associated with sagittal synostosis are beyond the scope of this chapter. Surgeons should apply the concepts and principles of cranial expansion and reassembly to choose the best technique for each patient.

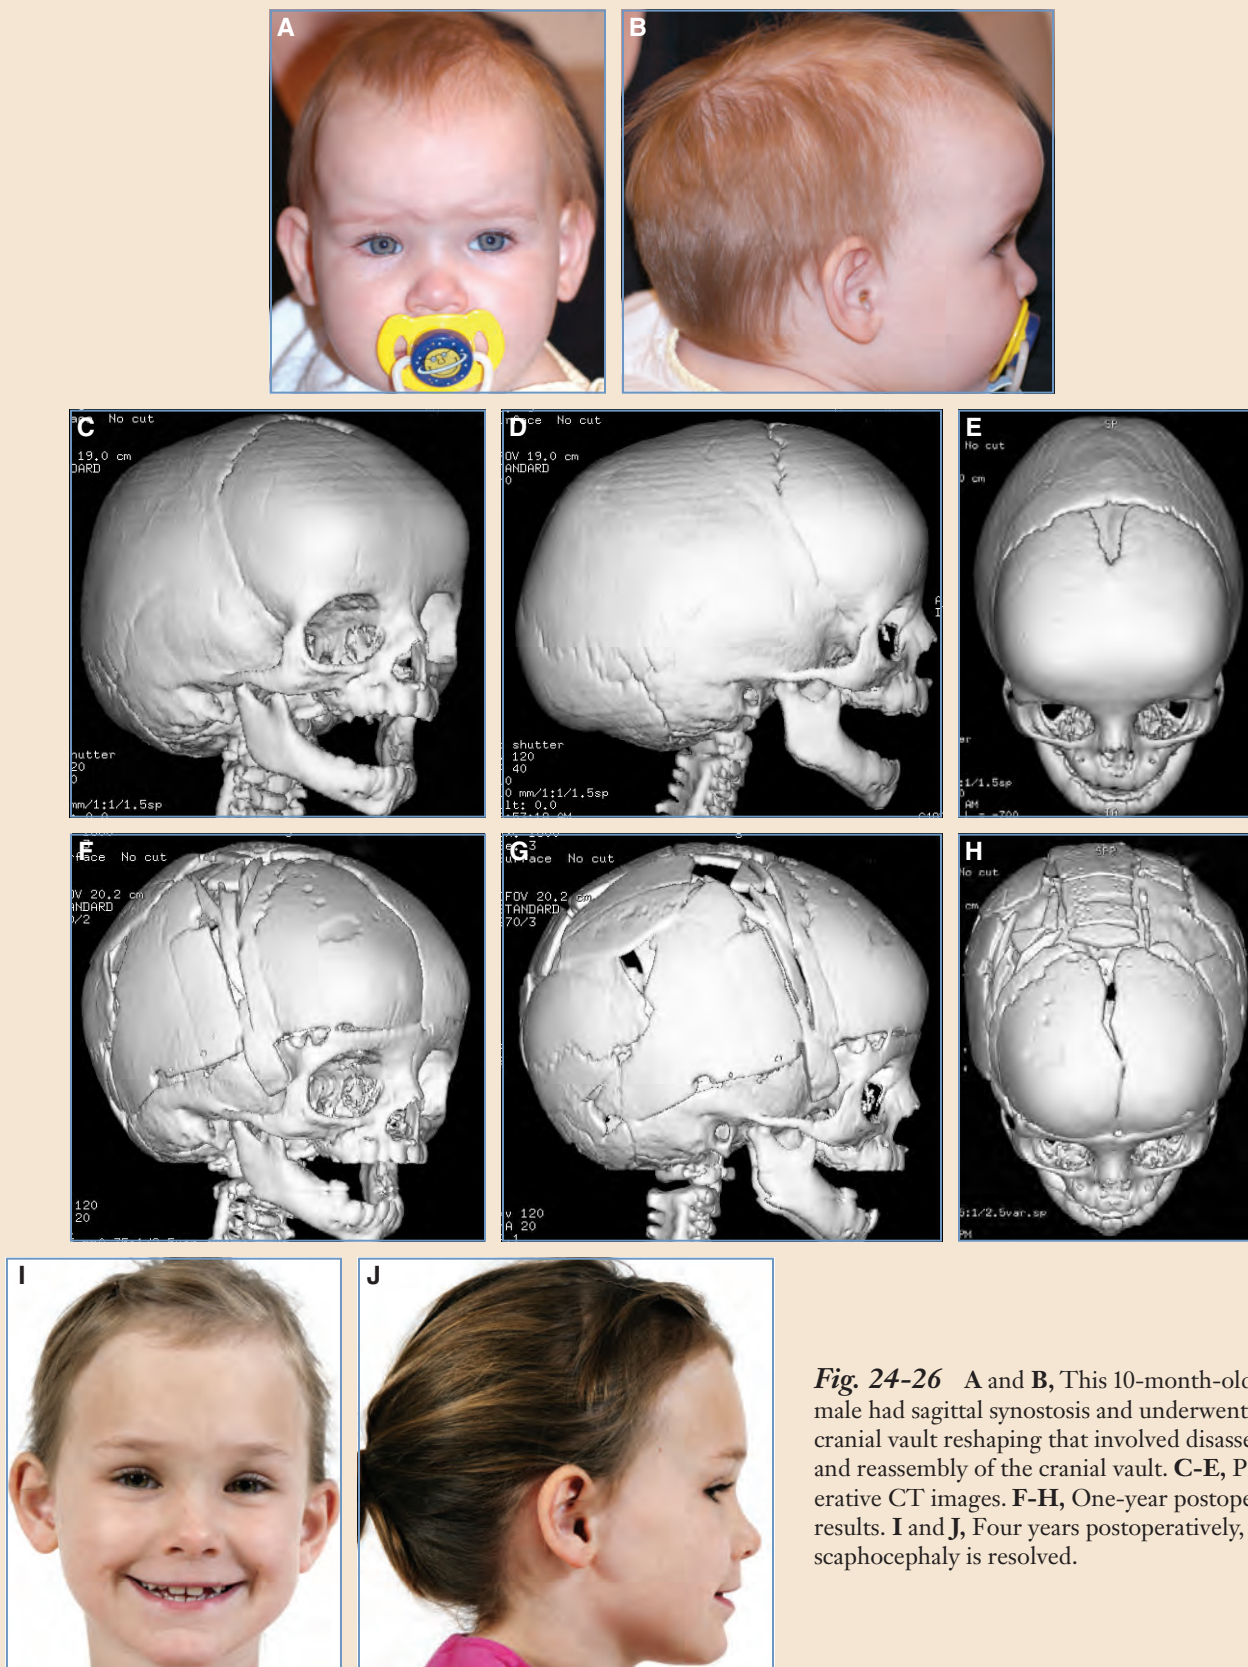

Fig. 24-26 A and B, This 10-month-old female had sagittal synostosis and underwent a total cranial vault reshaping that involved disassembly and reassembly of the cranial vault. C-E, Preoperative CT images. F-H, One-year postoperative results. I and J, Four years postoperatively, her scaphocephaly is resolved.

Other Techniques: Springs and Distractors

Springs have had wide application for managing many forms of single- and multiple-suture synostosis, in addition to posterior vault expansion surgery, discussed previously. Lauritzen et al⁹⁸ performed their original work at Sahlgrenska University Hospital in 1997. The procedure has been performed in centers around the world. In a young, pliable skull, a spring applied across a strip craniectomy will force the bone ends apart and remodel the adjacent cranial vault. Their use has evolved for managing patients with sagittal, metopic, and bicoronal synostosis. Critics of the technique cite the inability to control the degree and vector of expansion, possible erosion through the skin or through the dura, and difficulty removing the springs when they are enveloped by bone. However, once surgeons master the learning curve, the advantage of minimal intervention techniques and low-key technology, combined with experience, can produce satisfactory results.^{107,108}

Bone distractors have been applied to the cranial vault in patients with unicoronal, sagittal, and metopic synostosis. The advantages of not removing and reassembling bone fragments with fixation techniques are well-known. Disadvantages include the limited extent of correction, issues regarding vector control and cost, and the need for additional procedures to remove the devices. The optimal technique for the surgical management of craniosynostosis is not yet known, but having multiple options is invaluable.^{109,110}

Late Surgery

Craniosynostosis surgical intervention is recommended for patients 1 year of age or younger; however, many patients are not diagnosed until later in life. Several factors require consideration when treating older patients. The cranial bone is less malleable and more prone to fracture during manipulation. Cranial bone defect reossification is less robust and often requires split-skull bone graft during surgery or subsequent operations to fill the gaps.

Neurodevelopmental delays may not be identified until a child nears school age. Rarely, untreated craniosynostosis has caused intracranial hypertension and irreversible vision changes.

As mentioned previously, most single-suture craniosynostosis patients undergo a single intracranial procedure in the first year of life. However, because of facial asymmetry associated with unicoronal synostosis, bone defects, scar revisions, and areas of relapse, these patients are followed closely for several years and have the opportunity for additional surgery as needed (Fig. 24-27). The scope of management for syndromic patients is beyond the limits of this chapter but may involve a staged correction of hypertelorism, airway management with monobloc frontofacial advancement or LeFort III advancement, and definitive orthognathic surgery at skeletal maturity.

COMPLICATIONS

Surgery for craniosynostosis is considered a major, complex procedure performed on young infants with limited physiologic reserve. The potential for severe comorbidities (airway problems and intracranial hypertension) is high. These operations should be performed exclusively by a team of experienced health care professionals at a tertiary care center with adequate volumes. Despite the expertise and experience of such professionals, complications and, rarely, death occur from surgical intervention. Six of Tessier's fellows published the first report of complications in craniofacial surgery in 1979.¹¹¹ They described major morbidity and mortality rates of 16.5% and 1.6%, respectively.

Improvements in anesthesia and monitoring techniques, imaging, and technology resulted in shorter surgical times and significantly diminished mortality in large series. Most life-threatening

Fig. 24-27 These patients underwent a single procedure in infancy for treatment of a single-suture nonsyndromic synostosis. **A**, This patient presented with a mild right temporal hollow 10 years after correction of a right unicoronal synostosis. **B**, This patient had a bilateral superolateral orbital wall recession 11 years after correction of a metopic synostosis. **C**, This patient had residual facial asymmetry 10 years after a right unicoronal synostosis repair. She had discordance of orbital and dental midlines and periorbital asymmetry. **D**, Cranial defects after craniocorbital reshaping that persist in patients 5 years of age and older may require cranioplasty.

complications occur in the operating room and are related to blood loss and volume depletion, transgression of the venous sinuses, air embolism, and the effect of comorbidities such as cardiac disease and airway compromise. In a two-center review of 8100 intracranial and subcranial craniofacial procedures, the intracranial procedure major morbidity rate was less than 0.1%, and the combined mortality rate was 0.1%.¹¹² Subsequently, a Nationwide Inpatient Sample for 2004 through 2010 reviewed 17,788 hospitalizations for surgical repair in craniosynostosis patients up to 3 years of age.¹¹³ They reported a mortality rate of 0.8%. After hospitalization, 98% were discharged routinely. The five most frequently reported complications were hemorrhage (4.1%); iatrogenically induced complications, including accidental punctures, lacerations, and pneumothorax (3.1%); cardiac complications (0.7%); bacterial infections (0.7%); and respiratory complications (0.7%). No distinction was made between syndromic and nonsyndromic cases in either of these series.

In a recently published series of more than 700 intracranial procedures in nonsyndromic single-suture craniosynostosis patients, major complications occurred in 1.1% and minor complications in 3.5% of cases.¹¹⁴ Complications were increased with the presence of any comorbidity and in patients with metopic and sagittal synostosis.

A series of nearly 800 consecutive patients in Melbourne, Australia, had surgery for craniosynostosis from 1981 to 2010.¹¹⁵ Complications occurred in 14% of children, and 5.4% required a major revision surgery. Multivariate analysis helped to identify the following predictors of complications: multiple-suture and syndromic craniosynostosis, more recent surgeries, younger age (less than 9 months), spring-assisted cranioplasty, longer surgery, and greater transfusion volume. Patients with syndromic and multiple-suture craniosynostosis and those younger than 9 months of age at surgery had an increased risk of major revision surgery for regression to phenotype.¹¹⁵

Syndromic and multiple-suture synostosis patients are well-known to have higher rates of morbidity. McCarthy et al⁹⁵ documented their experience over 20 years at a dedicated craniofacial unit. They highlighted the complexity of care required with syndromic craniosynostosis patients and showed increased complication rates compared with those of isolated nonsyndromic single-suture craniosynostosis patients. Specifically, the incidence of major secondary procedures (36.8% versus 13.5%), perioperative complications (11.3% versus 5.0%), and secondary complications (44.7% versus 7.7%) were significantly increased in the syndromic cases.⁹⁵

Because corrective surgery requires significant periosteal stripping and craniotomies, major blood loss usually is expected. Strategies to minimize transfusion include hypotensive anesthesia, preoperative recombinant human erythropoietin, and intraoperative agents such as aminocaproic acid and tranexamic acid.¹¹⁶⁻¹¹⁹ Venous air embolus risk is well documented in children undergoing cranial procedures. Although hemodynamic compromise is rare, the incidence of asymptomatic air embolism may be as high as 82.6%, as assessed by precordial Doppler ultrasonography.¹²⁰ Lifting the cranial flap off the dura can result in a dural tear with CSF leakage. When this is recognized intraoperatively, direct repair with or without a pericranial patch is required. A fibrin sealant may be used as an adjunct for watertight closure. Infection is low at 2.5% to 3.2%.^{121,122}

The late complications are abnormal bone healing and impaired bone growth. Dura has osteogenic potential in patients up to approximately 18 months of age. Older children have an increased risk of persistent cranial defects compared with those younger than 1 year of age. Up to 5% to 20% of patients have incomplete ossification, correlating with age.¹²³⁻¹²⁵ Generally, for cranial defects larger than 2 cm at the initial repair, split calvarial bone grafts or particulate bone graft should be used. Subsequent defects may require a second-stage surgery with either additional bone graft or a cranioplasty. Multiple materials are available, including titanium mesh, polymethylmethacrylate, and more recently, custom computer-aided design and computer-aided manufacturing polyetheretherketone implants. Significant relapse of bone requiring additional remodeling after adequate internal fixation is uncommon. However, partial relapse has been observed. Causes can be multifactorial, including the age of the patient at the time of the surgery, the bone thickness or density, the potential molecular effects of the causative germ mutation, the severity of the deformity of the initial presentation, and the effect of cranial base restriction.

Unresolved Issues

The treatment of craniosynostosis has evolved significantly to become a safer and more predictable operation. Several issues are unsolved. Minimizing blood loss is paramount. Bony relapse and bone defects are not completely predictable. One of the biggest issues is the measurement of outcomes. No good measures are available to indicate the impact of major craniofacial surgery in children. This is an opportunity for the development of patient-reported outcome measures for the future.

FUTURE DIRECTIONS

The evolution of advances in craniofacial surgery over the past four decades has been profound. As medical care legislation increasingly focuses on outcomes-based assessments, the framework may shift toward increased efficiency and more predictable results. Computer-aided design and manufacturing may decrease surgical time and deliver improved precision and accuracy.¹²⁶ The next dimension in craniofacial surgery will focus on enhanced application of combined technologies such as imaging and robotic surgery. It will be an exciting time for those with more than a passing interest in this field.

KEY POINTS

- Craniosynostosis (premature fusion of the cranial sutures) may be classified by the number of affected sutures (single versus multiple), the cause (primary or secondary), nonsyndromic or syndromic, and the anatomic location (major sutures: sagittal, metopic, coronal, temporal squamosal, and lambdoid; minor sutures: frontosphenoidal and frontozygomatic).
- The metopic suture fuses by 8 to 9 months of age. All other sutures usually fuse in the third decade of life.
- Most single-suture craniosynostosis cases can be diagnosed based on a clinical assessment. Surgeons should understand that sutural growth allows bone to move at right angles to the suture (Virchow's law), and that single-suture craniosynostosis results in recognizable patterns of cranial dysmorphism. CT scans are not routinely required to diagnose major suture fusion.
- Sagittal suture synostosis is the most common form of single-suture craniosynostosis (1 in 2500 births), followed by metopic synostosis. Lambdoid synostosis is the rarest form of single-suture synostosis. Symmetrical single-suture synostosis (sagittal and metopic) is more common in males.
- Nonsyndromic craniosynostosis is much more common than syndromic craniosynostosis and accounts for up to 85% of cases. A multidisciplinary assessment includes craniofacial and plastic surgery, neurosurgery, ophthalmology, genetics, social work, nursing, and anesthesia assessments at a minimum.
- Suture fusion patterns in syndromic craniosynostosis cases often involve the coronal ring (paired coronal sutures, frontosphenoidal sutures, and sphenothmoidal sutures) and are frequently associated with midface retrusion, exorbitism, and hypertelorism.

Continued

KEY POINTS (continued)

- Craniosynostosis may be a component of up to 180 different syndromes, but Crouzon, Apert, Pfeiffer, Muenke, and Saethre-Chotzen are the more common syndromes seen. Syndromic craniosynostosis cases are quite complex and can be differentiated on the basis of an extremity examination. However, phenotypic differentiation is not always accurate and may require molecular genetic assessment (*FGFR*, *TWIST*, and *EFNB1*).
- Syndromic craniosynostosis cases require interdisciplinary team assessments, including CT, MRI, and vascular imaging to rule out hydrocephalus, Chiari malformations, and venous sinus anomalies.
- ICP may be increased in up to 50% of syndromic craniosynostosis cases and may result from craniocerebral disproportion, hydrocephalus, venous drainage anomalies, and obstructive sleep apnea. Detection of intracranial hypertension may be based on clinical findings (headache), although symptoms can be subtle or absent. Papilledema and bulging fontanelles may be present. ICP monitoring is considered to be the benchmark for assessing increased ICP.
- Surgical treatment of single-suture craniosynostosis may involve strip craniectomy techniques with molding helmet therapy, which is best performed in infants younger than 6 months of age. Patients older than 6 months of age have increased bone thickness and diminished brain growth, resulting in less cranial vault remodeling. Therefore surgical treatment in this age group requires the disassembly-reassembly cranioplasty techniques of anterior, posterior, or total cranial vault remodeling. A frontoorbital advancement is performed in patients with supraorbital rim retrusion or asymmetry.
- Surgical treatment of syndromic craniosynostosis is often staged and begins with cranial vault expansion and remodeling in infancy. Because of the higher reoperation rates, attention has recently been focused on addressing the posterior cranial vault initially and delaying treatment of frontofacial deformities. Delaying surgery may reduce the need for revision procedures. Frontofacial advancement, LeFort III, and orthognathic procedures are routinely carried out in syndromic craniosynostosis patients at specific developmental points depending on the indications.
- Syndromic and multiple-suture synostosis patients have higher rates of complications and morbidity.
- Despite best efforts, residual deformities can develop after surgical treatment. Therefore craniosynostosis patients should be followed at a recognized craniofacial center until the teenage years to provide the opportunity for correction of secondary deformities.

Hypertelorism

Jeffrey A. Fearon • Devan Griner

Hypertelorism is a descriptive term commonly used to signify an increase in the distance between the bony orbits.¹ This abnormality is not a specific pathologic entity but is a trait shared by many conditions. Strictly defined, hypertelorism is an abnormally increased distance between *any* two paired body parts; for this reason Tessier et al^{2,3} preferred the term *orbital hypertelorism*, or *hypertelorbitism* (sometimes shortened to *telorbitism*). Despite this preference, the term hypertelorism has persisted as the descriptor for any increased bony interorbital distance. *Telecanthus* refers to an increased intercanthal (soft tissue) distance. Although telecanthus always accompanies hypertelorism, the reverse is not always true—in some instances, there may be an increased intercanthal distance without true hypertelorism; for example, blepharophimosis or laterally displaced nasoethmoid fractures with disruption of the medial canthal tendon.

CONDITIONS THAT CAUSE HYPERTELORISM

In embryologic development, the optic vesicles arise laterally by the fourth gestational week; their medial migration occurs both as a primary process and secondarily as a result of rapid expansion and broadening of the cerebral hemispheres and temporal lobes. The final position of the optic vesicles is set at about the ninth week of gestation. Hypertelorism results when any condition interrupts this medial movement or when some midline structure, such as the ethmoid sinus or the brain, expands abnormally and pushes the orbits apart. The most common causes for hypertelorism are listed in Box 25-1; however, these conditions are not exclusive and may overlap. Given that hypertelorism is a phenotypic observation common to multiple conditions and syndromes, it is not surprising that there has not been a single gene found responsible for this trait. Instead, multiple gene mutations have been correlated with hypertelorism.

Box 25-1 Conditions Associated With Hypertelorism

- Craniofacial dysostosis
- Encephaloceles
- Facial clefting
- Frontonasal and craniofrontonasal dysplasia
- Miscellaneous: tumors; Greig, Opitz, and other syndromes
- Trauma
- Amnion rupture sequence

Fig. 25-1 CFND includes coronal synostosis (left-sided in this patient) in association with hypertelorism.

A relatively common cause of significant hypertelorism is *craniofrontonasal dysplasia sequence* (CFND). This is an atypical X-linked syndrome with variable penetrance; it occurs more often and is usually more phenotypically severe in females than in males. In most cases, this condition has been found in association with a mutation in the ephrin B1 (*EFNB1*) gene.⁴ Affected children present with a combination of both coronal synostosis (unilateral or bilateral) and frontonasal dysplasia, resulting in an asymmetrical hypertelorism that is frequently accompanied by a widow's peak and broad nasal tip.⁵⁻¹⁰ (Fig. 25-1). *Frontonasal dysplasia* is a condition similar to CFND except with no associated craniosynostosis; multiple subtypes have been identified, many of which are in association with mutations in the *ALX* homeobox genes 3, 4, and 1.¹¹ Hypertelorism may also result from facial clefting, amnion rupture sequence, or in association with encephaloceles. In particular, midline facial clefting may be associated with other midline intracranial anomalies. There may also be some correlation between midline facial clefts (Tessier number 14) and encephaloceles.¹² Encephaloceles may be the one exception to the belief that in most cases of hypertelorism, the distance between the optic canals is either normal or only slightly increased.¹³ When present, encephaloceles may exit the cranial cavity through one of multiple locations. When the encephalocele exits through the foramen cecum (a frontal encephalocele) or through the floor of the skull (a basal encephalocele), midline migration of the orbits is usually affected, resulting in *clinical hypertelorism*.

Significant facial trauma most often results in telecanthus, but it may also cause hypertelorism; however, in these cases, a component of vertical globe dystopia and significant asymmetry often accompanies the increased interorbital distance. Patients with craniofacial dysostoses (for example, Apert, Crouzon, and Pfeiffer syndromes and others) may present with a mildly increased interorbital distance (probably from compensatory lateral temporal expansion resulting from the inhibition of frontal growth). Finally, many miscellaneous causes, such as fibrous dysplasia, tumors, and syndromes such as Greig, Opitz, and others, share hypertelorism as a common phenotypic component.

PERTINENT ANATOMY

Various methods of measuring the interorbital distance have been reported that are based on absolute distances and ratios of different anatomic structures: intercanthal distance, interpupillary distance, interdacryon distance, canthal index, circumference-interorbital index, intercanthal palpebral fissure index, and other parameters.^{14,15} The interdacryon distance is probably the most commonly used measurement. Normal values for interorbital distance have been described based on anatomic and radiologic measurements¹⁶⁻¹⁹ (Table 25-1).

Günther²⁰ described the following grading system for hypertelorism in adults: first-degree (30 to 34 mm), second-degree (35 to 39 mm), and third-degree (40 mm or more), and it has been suggested that the surgical approach should vary based on severity. The obvious drawback to this classification scheme is that it is only appropriate for fully grown individuals. For a growing child, it is more practical to base treatment decisions on a percentage increase in interorbital distance instead of using absolute numbers; for example, grade I (up to 125% of normal/average); grade II (between 125% and 150%); and grade III (greater than 150%). A classification system for hypertelorism has also been proposed based on the location of the maximum width of the ethmoid sinuses, as viewed in the axial plane (anterior, medial, or posterior). Cases involving posterior ethmoidal widening are the most difficult to correct; surgeons must be cautious when reducing the posterior ethmoid sinuses, which lie close to the entrance of the optic canal.²¹ Despite the possible surgical implications, this classification system has not been widely adopted. Nevertheless, knowledge of the anatomy of the presenting deformity is critical to achieving a safe, satisfactory correction.

Table 25-1 Average Interorbital Distances and Intercanthal Distances According to Age

Age (yr)	IOD (mm)	ICD (mm)
Birth	16	20
1	18.5	25
3	21	26
5	22	27
7	23	28
12	26	29
Adult	27	30

ICD, Intercanthal distance; IOD, interorbital distance.

PREOPERATIVE ASSESSMENT

Hypertelorism does not always require surgical treatment. In fact, many consider mild hypertelorism an attractive trait. An examiner's perception of interorbital distance may be affected by the height of the nasal dorsum: individuals with a hypoplastic nasal dorsum may appear to have an increased interorbital distance, even if the measured distance is in the normal range. In addition, epicanthal folds, exotropia, widely spaced eyebrows, narrow palpebral fissures, and dystopia canthorum may contribute to an illusion of hypertelorism.¹³ It has been the senior author's experience (J.A.F.) that correction of hypertelorism is almost never required with craniofacial dysostoses. This is because the associated nasal and midfacial hypoplasia significantly contributes to the appearance of hypertelorism, but when this is appropriately corrected, the improvement in the patient's appearance is sufficient to avoid the need for an intracranial hypertelorism correction.

Axial, coronal, and three-dimensional CT scan reconstructions are important tools for surgical planning. Many surgeons find three-dimensional models constructed from CT data helpful to determine osteotomy locations and plan the movements of bony fragments.²²⁻²⁴ For cases involving encephaloceles, MRI scans provide important data for the neurosurgical aspects of the repair and help to determine the boundary between the disorganized encephalocele and the organized functional brain. Finally, preoperative ophthalmologic evaluations provide baseline visual data to which subsequent evaluations may be compared.

SURGICAL TECHNIQUE

Timing

The timing of surgical intervention has engendered some degree of controversy among craniofacial surgeons and ideally should be based on several factors. Children who present with encephaloceles or facial clefts involving absent skull will typically require earlier treatment. Extreme care must be taken in repairing telorbitism arising from basal encephaloceles, because these may contain the pituitary gland and/or the hypothalamus, and resection of the encephalocele may lead to panhypopituitarism. Children with severe hypertelorism may be unable to develop stereoscopic vision if treatment is delayed (although the efficacy of treatment with respect to the development of stereoscopic vision has not been well studied). One issue regarding surgical timing relates to what effect growth will have on the final result. Some reports have suggested that growth is not affected by surgical treatment, which opens the door to earlier surgical intervention, whereas others suggest that surgery has a negative impact on growth.^{9,15,19,25-29} It seems intuitive that the larger the surgical procedure and the younger the patient, the more likely that growth centers will be affected and that subsequent growth will be diminished. Most experienced surgeons will delay surgical correction until a significant amount of growth has occurred, yet before any serious psychological issues have developed (which usually occurs at 6 to 8 years of age, depending on the individual), which seems to result in better outcomes. It has also been suggested that surgical interventions before 8 years of age may lead to higher rates of bony interorbital relapse.²⁷

The treatment of children affected with CFND, one of the more common causes of severe hypertelorism requiring surgical intervention, presents a more complicated timing consideration for surgery. The combination of hypertelorism (ideal correction delayed until 8 years of age) with unicoronal or bicoronal synostosis (ideally corrected before 18 months of age) makes a staged-surgery strategy necessary. Kawamoto et al⁹ described an operative algorithm for CFND based on their 30-year experience; they advised earlier treatment of the craniosynostosis at 6 months (although today, we would argue for a later correction: between 11 and 18 months of age), followed by a hypertelorism correction after the central incisors erupt at 6 to 8 years of age. In their series, the only patients requiring secondary hypertelorism corrections were those operated on earlier than 5 years of age.

Choice of Procedure

Tessier³⁰ opined that surgical correction for telorbitism is essentially surgery of the nose. Although correction of the associated nasal deformity is a critical finishing step in the treatment of hypertelorism, medial transposition of the globes is nevertheless a significant surgical undertaking. Numerous osteotomies have been described for correcting hypertelorism. To decide which of these techniques is the best approach, it is helpful to consider the underlying cause of the hypertelorism, the degree of separation, and the patient's age. The surgical treatment of hypertelorism is both one of the more complex and least commonly performed operations by craniofacial surgeons. The following description of the surgical techniques is presented as a general overview and should not be considered a surgical atlas.

Two-Wall, Three-Wall, and Four-Wall Osteotomies

Treatment of the mildest degrees of hypertelorism may be accomplished by performing *two-wall osteotomies*—superior and inferior osteotomies of both the medial and lateral orbital walls. The medial orbital walls are infractured or medially translocated after removal of a central strut of nasal dorsum, perpendicular plate, and posterior ethmoid sinuses, sufficient to permit medial globe translocation. The lateral orbital walls are then shifted medially, which moves the globes (Fig. 25-2). The medial movement of the lateral walls is responsible for reducing the distance between the globes in each of the different types of hypertelorism corrections. Simply shifting the medial walls more medially without moving the lateral walls will have no significant effect on globe position. The two-wall technique may be performed completely extracranially, avoiding the need for neurosurgical assistance, but care must be taken to preserve symmetrical orbital widths after translocation.

The *three-wall osteotomy** technique preserves the relationship of the orbital roof (or the orbital floor) to the medial and lateral walls, which in turn maintains the orbital width during translocation. If the width of the piriform aperture is normal, then any medial movement of the orbits will compress the nasal passages; therefore bone removal from the edges of the piriform aperture may be necessary to preserve the nasal airway. One advantage of the *U-shaped osteotomy*,

*The terms *three-wall* and *four-wall osteotomies*, although useful descriptors, are misnomers, because the orbit is composed of only two walls, along with a roof and a floor.

Fig. 25-2 Smaller orbital translocations can be achieved with two-wall osteotomies. The medial orbital walls are infractured, and the lateral orbital walls are moved medially, taking care to maintain normal orbital width.

Fig. 25-3 U-shaped osteotomies include the orbital floor, with the medial and lateral walls as a single unit. These osteotomies exclude the orbital roof, avoiding the need for an intracranial approach.

Fig. 25-4 Reverse U-shaped osteotomy includes the orbital roof with the medial and lateral walls, eliminating the orbital floor osteotomy. This procedure requires a craniotomy, but it may be technically easier than the U-shaped osteotomy.

Fig. 25-5 The traditional four-wall osteotomy can be made either **A**, above the infraorbital foramen (in older children), or **B**, below the infraorbital foramen. However, osteotomies going below the infraorbital fissure may increase the risk of dental root injury.

which preserves the orbital floor (Fig. 25-3), is that this approach is completely extracranial. However, a disadvantage of this technique is that the infraorbital osteotomy can be difficult to perform without injury to the infraorbital nerve, lacrimal fossa, and unerupted tooth buds, especially in younger children. The *reverse U-shaped osteotomy* has several advantages: it leaves the orbital roof intact and is technically less challenging, the osteotomies are more easily visualized, and the maxilla is left intact (Fig. 25-4). The primary disadvantage of this supraorbital approach is the need for intracranial access.

Four-wall osteotomies (“box osteotomies”) are generally reserved for the most severe cases of hypertelorism and are generally undertaken in skeletally mature patients (Fig. 25-5). With this technique, osteotomies are made above the orbital roof and below the orbital floor, and the orbit is circumferentially cut in the coronal plane posterior to the midportion of the globe. Medial translocation is achieved by removing a central section of nasal bone, perpendicular plate, and posterior ethmoid sinuses. This approach provides complete mobilization of the orbits, allows more significant translocations, and may result in greater final stability.

Facial Bipartitions

Facial bipartitions are probably the most frequently performed hypertelorism correction technique for children, especially those who have any condition that has produced a midline separation of the face (for example, facial clefts and encephaloceles). One reason for this is that this technique avoids the need to perform a horizontal maxillary osteotomy, which might damage the roots of the teeth during the mixed dentition phase. This technique requires intracranial exposure, and in addition to bringing the orbits closer together, lowers the midline of the maxilla through a rotational movement of the lateral facial halves (Fig. 25-6).

A facial bipartition is also useful for children with significant midline vertical shortening of the maxilla, palate, and upper dental arch.^{31,32} Osteotomies are performed through the orbital roofs, medial and lateral walls, and floors in the coronal plane, as with a four-wall osteotomy. However, unlike the four-wall osteotomy, no horizontal maxillary cuts are made below the orbit. Instead, a pterygomaxillary disjunction is performed sagittally to allow the hemimaxilla to

Fig. 25-6 Facial bipartition results in both **A**, a medial translocation of the orbits and **B**, flattening of the upper occlusal plane by rotating the facial halves through a lower central maxillary axis.

move in continuity with the orbit. This disjunction may interfere with future facial growth (and subsequent eruption of molars), depending on the child's age. Although modifications have been described that are intended to avert growth inhibition, the subsequent postoperative preservation of normal facial growth remains undocumented.³³ The facial bipartition technique creates larger bone segments for translocation than does the four-wall osteotomy technique, which may enhance final stability. In extremely rare instances of severe hypertelorism with significant increases in interoptic nerve distance, a staged correction should be considered to avoid the potential loss of vision from optic nerve tension after significant movement of the orbits (Figs. 25-7 through 25-9).

Fig. 25-7 Large encephaloceles may create a significant diastasis between the optic nerves, which is not typically seen in most other causes of hypertelorism.

Fig. 25-8 **A**, A child with hypertelorism (resulting from an encephalocele) is seen preoperatively. A staged correction was planned to reduce the substantially increased distance between the optic nerves, based on concern for loss of vision. **B**, The same child is shown after the first stage of a bipartition procedure. A superior dog-ear is left unresected to limit the length of the skin incision. **C**, The child is shown after the second stage of the bipartition procedure.

Fig. 25-9 Typical hypertelorism (see Chapter 35 for a case of atypical hypertelorism). **A**, Patient at infancy. **B**, Patient at 14 years of age with asymmetrical hypertelorism (atypical craniofacial cleft, bilateral Tessier 12-13). **C**, Preoperative three-dimensional CT scan. **D** and **E**, She underwent "box" orbital osteotomies at 15 years of age, followed by a nasal dorsal rib graft at age 16. **F**, Postoperative image at 17 years of age. The excess forehead skin was managed with an internal cinch suture. Further surgery is planned to aesthetically define the medial supraorbital rim and brow. (Courtesy of Pravin Patel, MD.)

TECHNICAL ASPECTS

We recommend a conservative approach to treat milder hypertelorism, not only because many individuals consider mild hypertelorism an attractive trait, but also because of the unfavorable risk-benefit ratio. Significant risks are associated with these major procedures, and in milder cases only limited enhancements in appearance can be expected. This philosophy restricts treatment to more severely affected individuals, and therefore the choice of osteotomies is narrowed to either a bipartition or a four-walled technique. Surgeons without significant pediatric congenital craniofacial experience are well advised to seek the assistance of more experienced surgeons when faced with a child who has significant hypertelorism.

Moderate-to-severe hypertelorism corrections begin with a low frontal craniotomy following an extensive dissection of the nasal bones, orbits, anterior zygoma, and maxilla. The low frontal craniotomy should be sufficiently wide to provide a clear view of the entire orbital roof and anterior tip of the temporal lobes, which need to be retracted while lateral orbital osteotomies are performed. An upper buccal sulcus approach is necessary with facial bipartitions to separate the midline of the palate or when performing box osteotomies if the low horizontal maxillary osteotomy is planned below the infraorbital foramen. After the frontal craniotomy, the width of the midline nasal resection is determined and marked, and cuts are made with a short saw blade to excise the central vertical strip of nasal bones; removing the posterior perpendicular plate of the ethmoids may help to further reduce the intraorbital distance. Osteotomies are made across the orbital roof anteriorly and then lateral to the lateral orbital walls to include as much of the posterior lateral wall as possible. Next, a horizontal cut is made below the inferior orbital rim, retaining sufficient bone to provide inferior stability, yet avoiding injury to the inferior orbital nerve. This low cut must continue medially into the vertical midline gap, which was created by removal of the central portion of the nose. Osteotomies are completed along the orbital floor anteriorly and down the medial orbital wall (or the medial wall can be removed).

For a bipartition, the low horizontal cut across the maxilla is replaced by continuing the lateral orbital osteotomy, which preserves as much of the lateral orbital wall as possible, into the pterygoid fossa to separate the pterygomaxillary junction. If the maxillary midline is intact, a limited upper buccal incision allows access to the hard palate. The hard palate is split along the midline with a narrow osteotome after the nasal mucosa is freed up along the floor of the nose and the inferior portion of the septum is detached from the vomerine groove. The two orbital boxes are then medially translocated.

With the bipartition procedure, each lateral facial segment is translocated, with the axis of rotation centered above the central incisors. We have found it helpful to place a temporary wire around the central incisors to prevent the creation of an unsightly gap between these teeth. In our practice, the medial orbits are held together with a monofilament absorbable suture such as 2-0 PDS, and the frontal bone is subsequently reattached with the same suture material. Our preference for absorbable suture material rather than resorbable sutures or metal plates is based on ease, speed of fixation, and low infection rates.³⁴

Medial canthopexies are then performed, also with the use of PDS sutures. The decision to primarily bone graft the nasal dorsum depends on the dorsal height of the paired nasal bones. After the coronal incision is closed, consideration is given to resecting the nasal skin through a midline excision. If skin needs to be removed, acceptance of a small dog-ear following a limited excision length is recommended, because this will flatten out over time.

POSTOPERATIVE CARE

Children undergoing hypertelorism correction require highly skilled postoperative pediatric intensive care monitoring. We do not use surgical drains or postoperative bandages, and children are routinely extubated in the operating room. Frequent neurologic checks and visual evaluations are performed, in addition to careful monitoring of hemoglobin levels, acid-base status, and serum electrolytes (observing for hyponatremia, indicating the possibility of a syndrome of inappropriate antidiuretic hormone, and hypokalemia, which may be induced if sodium bicarbonate is administered to correct acidosis). Typically, children require one to two nights of intensive care observation before they are sufficiently stable to permit safe transfer to a general unit. When hypertelorism corrections are performed in conjunction with basal encephalocele repairs, postoperative hormonal monitoring of pituitary and hypopituitary function is necessary.

COMPLICATIONS

Although not typically considered a complication per se, the inability to achieve a reasonably normal long-term appearance after surgical correction of hypertelorism is probably the most commonly encountered adverse outcome. In most instances the primary motivating factor to undertake a hypertelorism correction is to improve appearance, yet the ability to actually achieve a normal postoperative appearance can be extremely challenging. The reasons for suboptimal outcomes remain a matter of ongoing debate.^{9,15,26-28} Despite the commonly seen suboptimal hypertelorism correction results, most patients and their families report satisfaction with their surgery.^{28,35}

Few centers have the facilities and experience to provide these types of treatment, and even fewer centers have the volume of patients necessary to acquire the requisite experience to reproducibly and safely correct these rare anomalies. Given the rarity of this condition, there have been only a few published series of hypertelorism corrections coming from the busier centers; for this reason, complication rates are difficult to ascertain.

Among the objectively traceable complications, infection probably ranks as the most frequently encountered adverse outcome. Intuitively, infection rates for hypertelorism corrections should be higher than rates after isolated craniosynostosis corrections, because hypertelorism-associated osteotomies routinely traverse sinus cavities. Most craniofacial infections do not present clinically until about 10 days after surgery, but if prompt treatment is undertaken, bone loss may be minimized.³⁶ Brain injury is extremely uncommon, aside from the treatment of hypertelorism resulting from basal encephaloceles. In addition to infections, cerebrospinal fluid leaks, anosmia, major relapse, and postoperative ptosis have been reported.^{21,25,37,38}

KEY POINTS

- Hypertelorism is a descriptive term and not a diagnosis.
- Mild cases of hypertelorism do not require surgical treatment.
- Medial movements of the *lateral* orbital walls are required to significantly reduce the distance between the globes.
- Intracranial hypertelorism corrections are uncommonly performed procedures and may be associated with elevated surgical risks.
- Although the medial translocation of the globes is a significant surgical undertaking, the correction of associated nasal deformities is the critical finishing touch.

The authors reported their analysis of the EFNB1 gene in three families with craniofrontonasal syndrome. In one family, a deletion of exons 2-5 was identified in an obligate carrier male, his mildly affected brother, and in the affected females. In the other two families, missense mutations in EFNB1 were detected, which led to amino acid exchanges P54L and T111I. In all cases, mutations were found consistently in obligate male carriers, clinically affected males, and affected heterozygous females. The authors concluded that mutations in EFNB1 cause craniofrontonasal syndrome.

Atypical Craniofacial Clefts

Pravin K. Patel • Henry K. Kawamoto, Jr.

he word *face* has many meanings, especially when we consider the relationship that we have with our own face. Outwardly, our face is our appearance, as we would like it to be, whether it is through the eyes of others or the image that we see reflected in a mirror. Inwardly, to some degree, our face reflects our self-worth. Our face represents our dignity and integrity; in addition, it serves as our facade and mask. This inner and outer relationship we have with our face is entwined.

Now consider when a crack runs through a face and sees itself reflected in a mirror, shattered. Is it still a face? How do we describe what remains? The child born with a craniofacial cleft is left with a sense of disfigurement and isolation. Regardless of the surgeon's attempts to restore the physical structure of the face, it is the child who reassembles and reconstructs the face from the inside out. Perhaps no other singular deformity distorts the face as much as when it is fractured by a cleft.

The meaning of the word *cleft* is apparent and easily understood when one is faced with a clinical example, such as a cleft lip or palate. However, not all defects in the apposition of junctional structures are so obviously definable as a cleft, or as easily classified. Rare or atypical clefts manifest in myriad patterns of clinical expression. This chapter includes a discussion of the developmental processes by which they may occur, an attempt to order the vast array of craniofacial clefts, and their management.

INCIDENCE OF RARE CLEFTS

The exact incidence of rare or atypical craniofacial clefts is unknown. Because of the increasing unlikelihood of finding a specific event, it is more difficult to assign a reliable number. Moreover, there is no consensus on the definition of atypical clefts. Conditions regarded as hypoplasia may

Table 26-1 Incidence of Atypical Cleft

Series	Total Number of Cleft Cases Reviewed	Number of Atypical Clefts	Ratio of Atypical to Common Clefts
Davis (1935) ⁴	946	9	10:1000
Burian (1957) ⁵	4000	97	24:1000
Fogh-Anderson (1965) ⁶	3988	48	12:1000
Popescu (1968) ⁷	1475	14	10:1000
Pitanguy (1968) ^{7a}	736	25	34:1000
Ortiz-Monasterio and Taylor (1987) ⁸	5586	174	32:1000

in reality be clefts. Treacher Collins syndrome and hemifacial microsomia should probably be included within the category of clefts. *Forme fruste* and incomplete forms of the cleft may be so minor as to go unnoticed. The incidence depends not only on the awareness of the investigator but also on the taxonomy of the facial cleft that he or she prefers.

What we are more certain of is the incidence of common clefts of the lip and palate. Cleft lip occurs at an approximate rate of 1 in 1000 live births in the white population.¹ The condition is more prevalent among the Japanese, 2.1 per 1000 births, and less common in blacks, 0.4 per 1000 births.^{2,3} It is within this context of the common cleft that the best estimate of the incidence of atypical facial cleft can be obtained. In the few published reports of a large series of patients with common clefts of the lip and palate, there is a wide range of incidences of atypical clefts⁴⁻⁸ (Table 26-1). Smaller series are even less dependable in determining the incidence of these clefts.

In a group of 937 patients with a cleft of the lip and palate, Davis⁴ found four median clefts of the lip and five oblique clefts of the face. This yielded an incidence of unusual facial clefts of 9.6 per 1000 common clefts. Burian⁵ found an incidence of 24.3 atypical facial clefts per 1000 of all cleft types in a series of 4000 clefts over a 40-year period. In a study of 3998 patients with clefts, Fogh-Andersen⁶ reported an incidence of 12 rare clefts per 1000. Of the 48 rare clefts, 15 were median clefts of the lip, 12 were transverse clefts, 8 clefts were of the nose, 7 clefts were of the scalp, 3 were oblique, and 3 were atypical clefts. Popescu,⁷ who specifically looked at transverse facial clefts alone in a group of 1475 patients, found an incidence of 9.5 per 1000. Most recently in a series of 5586 patients with clefts over a 20-year period, Ortiz-Monasterio and Taylor⁸ reported an occurrence rate of 31 atypical clefts per 1000 common clefts.

Thus the incidence of rare craniofacial clefts ranged from 9.5 to 31 per 1000 common clefts.^{9,10} How rare then is an atypical cleft? Although extrapolating these numbers to the total number of births would be erroneous, we can obtain a rough estimate, albeit only to an order of magnitude. If we accept that the incidence of the common cleft lip is 1 per 1000 live births, then an atypical cleft would be seen 100 times less frequently in the general population, and we would expect the incidence to be on the order of 1 per 100,000 births. The incidence varies not only because of its true prevalence in the population, but also with investigator awareness regarding which specific clefts were included as atypical. Within our current understanding of craniofacial clefts, the most reliable figures were those obtained by Ortiz-Monasterio and Taylor.⁸

ETIOLOGIC FACTORS AND MORPHOGENESIS OF FACIAL CLEFTS

The origins of the embryologic forces that lead to clefts are unknown. The wide spectrum of abnormalities seen may be related to slight differences in the timing, duration, or intensity of genetic and environmental insults. Differential effects in the germ layer may play a role in the phenotypic variation. Except for Treacher Collins syndrome and Goldenhar syndrome (when considered as a cleft), genetics appears to play a limited role.¹¹⁻¹³ Moreover, because atypical craniofacial clefts are rarely clinically observed or we are unable to develop a reproducible animal model, most experimental work on nongenetic factors has been performed on clefts involving the lip and palate, the most common of the facial clefts. Among the causative factors, radiation, infectious agents, metabolic imbalances, and numerous drugs and chemicals have been implicated.¹⁴⁻²⁴ Teratogenic agents in craniofacial clefting have been extensively reviewed in the literature by Kawamoto.^{9,10} Extrinsic mechanical factors from an amniotic band disruption mechanism have been suggested to explain aberrant locations of clefts not corresponding to any well-described embryologic process.²⁵⁻²⁷ Vascular disturbances have been implicated in hemifacial microsomia.²⁸⁻³²

Although it is difficult to implicate the genetic role in the vast majority of atypical clefts, the genetic basis of mandibulofacial dysostosis or Treacher Collins syndrome has more recently been established.³³ New techniques in developmental biology and molecular genetics have mapped the human genome, and with it, approximately 70 genes related to craniofacial anomalies.^{34,35} Gene linkage studies in families with clear autosomal dominance of mandibulofacial dysostosis have led the search for the causative gene to chromosome 5q31.1-q33.3.^{36,37}

As a group, craniofacial clefting is both etiologically and pathogenetically heterogeneous.^{9,10} The gaps in our understanding between causative factors, whether genetic or epigenetic, morphologic development, and its final phenotypic clinical expression are large in the vast majority of cases.³⁸ Nevertheless, an understanding of normal embryologic development forms the basis on which we understand the deviations that may occur during pathologic development.

Embryology

The structural development of the cranium and face occurs between the third and eighth weeks of gestation when fetal length measures approximately 2.0 to 31 mm.³⁹⁻⁴⁴ Fig. 26-1 is a synopsis of the relevant embryology.

Week 3: Carnegie Stages 7 Through 9, 0.4 to 2.5 mm Gestational Length

The embryo begins as a two-dimensional planar structure, and just before the third week, the stage is set for the development of the central nervous system in the area of ectoderm thickening known as the *neural plate*. A midsagittal groove appears as a result of invagination of the ectoderm centrally and simultaneous elevation of ectodermal tissue alongside the groove to form the neural folds. These folds then fuse with each other in the midline, beginning at the junction of the future brain and spinal cord, to form the neural tube. As the folds fuse, there is a separation of the neural tube from the overlying ectoderm, of which it is derived. A population of ectodermal cells adjacent to the neural fold and not included in the overlying surface (somatic) ectoderm gives rise to the formation of the neural crest. These neuroectodermal crest cells are believed to migrate widely throughout the developing embryo in a relatively cell-free-enriched extracellular matrix and differentiate into a wide array of cell and tissue types, influenced by the local environment. Most of the connective and skeletal tissues of the cranium and face are ultimately derived from derivatives of neural crest cells.

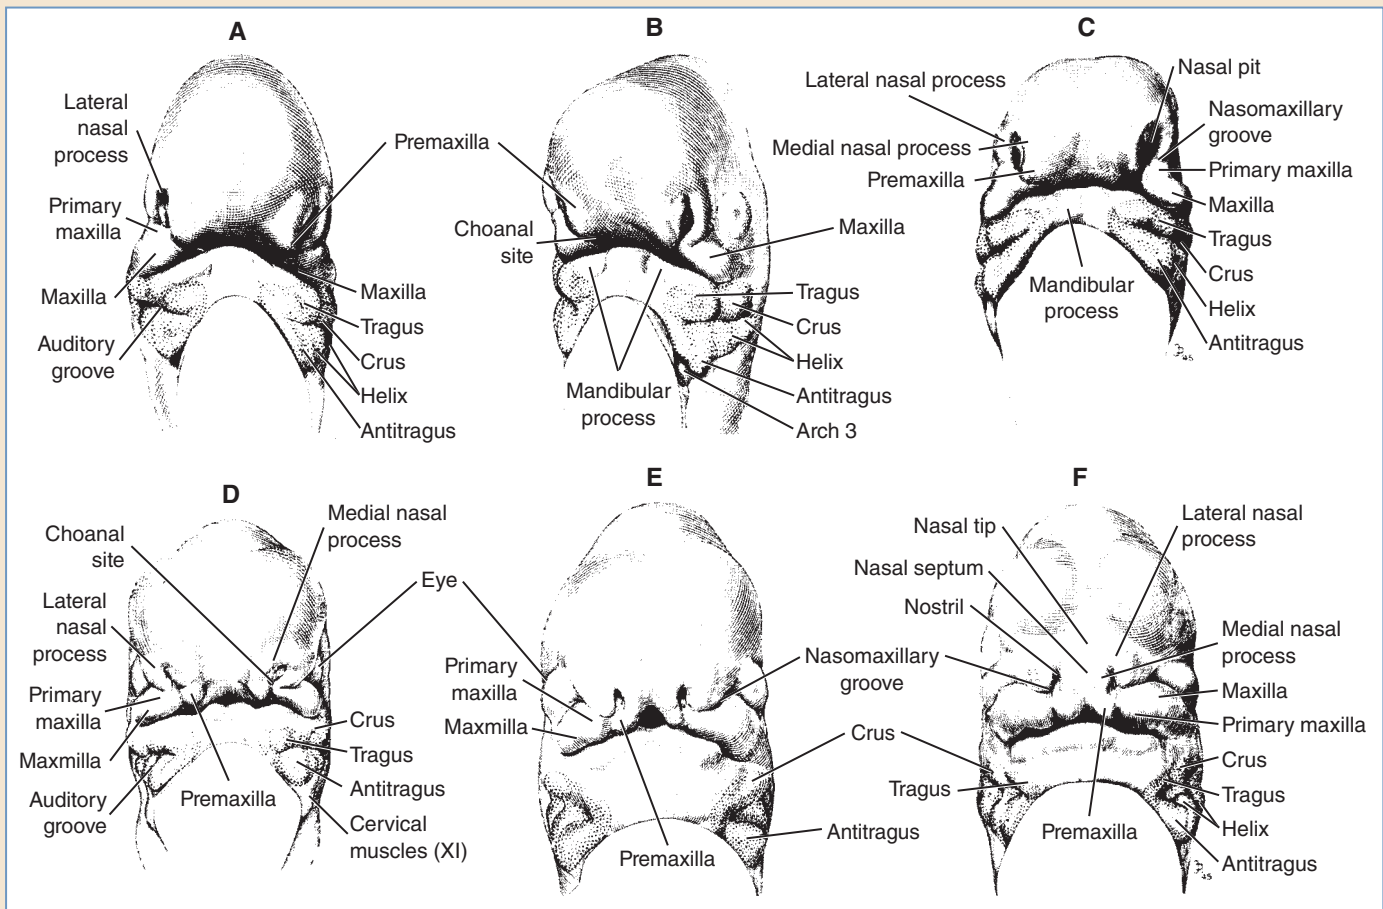

Fig. 26-1 Embryonic development of the face. **A-C**, Progressive development through stage 16, approximately 37 days' gestation, 8 to 11 mm. **D-E**, Development through stage 17, approximately 41 days, 11 to 14 mm.

The first morphologic evidence of the optic primordia is seen as a thickened area with a shallow sulcus on the lateral forebrain of the neural tube in the region of the future diencephalon. During the week, the optic sulcus deepens, and the surrounding walls form an evagination, which at first is in contact with the overlying ectoderm. Neural crest cells intervene between the optic vesicle and overlying ectoderm and give rise to specialized neuroectodermal elements of the eye and adnexa.

As the neural tube fuses cranially, closing off the anterior neuropore, a mesencephalic flexure occurs and the major divisions of the brain—*prosencephalon* (forebrain), *mesencephalon* (midbrain), and *rhombencephalon* (hindbrain)—can begin to be distinguished. By the end of the third week, further growth of the cephalic portion of the neural tube gives rise to the frontonasal process and branchial arches—the first stages of a recognizable face.

Week 4: Carnegie Stages 10 Through 13, 2.0 to 6.0 mm Gestational Length

The recognizable face begins its development from five primordia that surround a central area of depression, the oral pit or stomodeum. These primordia are a single cranially located fron-

tonasal process, two bilaterally located maxillary processes, and mandibular processes. The maxillary and mandibular processes are derived from the first branchial arch. These processes or masses grow differentially, and by obliterating the ectodermal plates or grooves between them, eventually give rise to the features of the face. The mandibular processes are the first to merge with each other at the midline and will eventually give rise to the mandible and lower part of the face and tongue.

During the fourth week the primitive trisegmented brain further subdivides. The prosencephalon (forebrain) divides into the telencephalon (endbrain) with prominent lateral domes (cerebral hemispheres) and the diencephalon, which gives rise to the optic vesicles. The mesencephalon remains in flexed cephalic flexure and undivided. The rhombencephalon divides into the metencephalon (cerebellum and pons) and the myelencephalon (medulla). By the end of the fourth week, the fundamental organization of the future brain is clearly identifiable.

The ectoderm overlying the optic vesicle of the developing eye thickens to form the lens placode. During the week, the optic vesicle deepens to form a goblet-shaped, double-layered optic cup as its stem narrows to form the optic stalk in continuity with the diencephalon. The frontonasal process intervenes between the two lateral optic cups, and at this stage the developing eyes are nearly 180 degrees apart.^{43,45}

Week 5: Carnegie Stages 14 and 15, 5.0 to 9.0 mm Gestational Length

Toward the end of the fourth week, nasal placodes develop bilaterally at the inferolateral corners of the frontonasal process. As the region surrounding the nasal placodes develops into medial and lateral nasal processes, the deepening nasal placodes are transformed into nasal pits, which in time form the anterior nares. With continued ectodermal development, the nasal placodes become olfactory grooves that at this stage are in continuity with the developing oral cavity. The maxillary processes continue to enlarge, encroaching on the stomodeum, to form a primitive oral cavity.

As the optic stalk narrows further to define the primitive optic nerve, retinal pigment appears in the external layer of the optic cup, and the inner layer begins to differentiate into the neural elements of the retina. The primitive vitreous body develops in the intervening space as the lens placode invaginates toward the optic cup to form a lens vesicle detaching itself from the overlying ectoderm.^{43,45}

As the features of the face form, the development of the embryonic skull begins. The mesenchyme surrounding the developing primitive brain condenses to form a mesenchymal capsule, the *desmocranium*. At about the fifth week, the base thickens, forming the cartilaginous cranial base through neuroectodermal condensation of the mesenchyme. In contrast, the calvarium develops by direct membranous ossification without a cartilaginous precursor later in the embryonic period.⁴⁶

Week 6: Carnegie Stages 17 Through 19, 8.0 to 14 mm Gestational Length

The medial nasal processes approach each other to form a single globular process that in time will give rise to the nasal tip, columella, prolabium, frenulum, and primary palate. As this occurs, the frontonasal process collapses inward to form the nasal septum. Continued growth of the maxillary mass below the optic vesicles allows fusion with the lateral nasal process. As fusion occurs, a sinking troughlike epithelial groove demarcates the nasooptic furrow connecting the conjunctival lacrimal sac with the lateral nasal wall. The epithelial groove fuses as a solid epithelial cord and eventually canalizes later in fetal development to become the nasolacrimal duct.⁴⁷ Toward the end of week 6, the maxillary process fuses with the medial nasal fold of the globular process, forming a true nostril as it gives rise to the lateral lip element (Fig. 26-2). However, posterior to this anterior fusion of the maxillary process to the nasal processes, the developing nasal floor is open to the oral cavity. Within the primitive stomodeum, lateral palatine processes develop from

Fig. 26-2 Contributions of the embryonic processes to the final emergence of the face.

the medial edges from the maxillary process to give rise to the secondary palate. At this stage, the developing tongue nearly completely fills the oral nasal cavity and reaches the nasal septum.

Simultaneously, the eye continues its development as neurocrest mesoectodermal cells at the lateral aspect of the lens differentiate into the early cornea and sclera. The cavity of the optic stalk is obliterated as nerve fibers from the retina grow back to reach the brain to form the optic nerve. The overlying surface ectoderm develops subtle horizontal folds with a mesenchymal core above and below the developing cornea that represent the beginning of the upper and lower eyelids.^{43,45,48}

During this sixth week, the external ear develops from six mesenchymal swellings (hillocks) that surround the first branchial cleft. The first three hillocks arise from the mandibular arch (first branchial arch) and the second three arise from the hyoid arch (second branchial arch) (Fig. 26-3). From ventral to dorsum, the hillocks of the first arch become the tragus, helix, and cymba concha; the hillocks on the second arch, the antitragus, antihelix, and concha. The branchial cleft lengthens to form the primordium of the external auditory canal. As the face develops, the auricle is gradually repositioned to a more lateral cephalic position from the original location low on the side of the neck.⁴⁵

Week 8: Carnegie Stages 20 Through 23, 18 to 31 mm Gestational Length

By the eighth week, the face has acquired a more human appearance, with complete closure of the lower facial fissures or grooves. The primitive upper and lower jaws are formed with complete fusion of the maxillary and mandibular processes. The upper lip and lower nasal regions are better defined. As it lengthens vertically, the frontonasal process continues to collapse horizontally, forming a transverse furrow at the nasal bridge. As the frontocranial region loses its overhang, the eyes begin to take a more medial position. The anterior rotation of the eyes continues throughout the remainder of the gestational period and well into childhood (Fig. 26-4). The upper and lower lids continue to develop and assume a more almond shape as they begin to fuse with each other (separation of the lids does not occur until weeks 25 to 26). The lined ectodermal-derived

Fig. 26-3 Development of the external ear illustrating the contribution of the hillocks from the first (1-3) and second branchial arches (4-6).

Fig. 26-4 Progressive medial rotation of the orbit and ocular globe through gestation and into adulthood.

epithelium between the fused eyelids and the cornea develops into the conjunctival sac and from the superolateral angles, the lacrimal glands.⁴³

The development of the skull continues, with ossification centers arising within the *mesenchyme* (membranous ossification) adjacent to the developing brain to form the flat bones of the calvarial vault, the paired frontal and parietal bones (Fig. 26-5). In contrast, the primordial elements of the chondrocranium begin to undergo endochondral ossification to form the bones of the *basicranium* (sphenoid, petrous part of the temporal and occipital bones) and nasal ethmoid significantly later in fetal life. The sphenoethmoidal and sphenooccipital synchondroses and septal cartilage persist to allow the forward growth of the cranial base and simultaneously to allow the inward rotation of the developing orbital complex.^{46,49,50}

In the face, small nasal bones appear above the nasal capsule, the cartilaginous model. On the lateral surface of the nasal capsule, premaxillary and maxillary ossification centers appear. Posteriolateral to the developing maxillary bone, ossification centers arise within the zygomatic

Fig. 26-5 Development of the craniofacial skeleton. Mesenchymal formation of the facial bones derived from neural crest cell contribution (*stippled areas*).

and squamosal portion of the temporal region. The mesenchyme encompassing Meckel's cartilage undergoes membranous ossification to form the body of the mandible. In time, Meckel's cartilage disappears and persists as the incus and malleolus of the middle ear. The onset of bone formation marks the end of the embryonic period, and the developing fetus is generally much more resistant to teratogenic insults.⁴⁴

Within this short period of 5 weeks, when the mother may be unaware of her own pregnancy, the face of her child has emerged. Any error that occurs in these tightly sequenced events of early facial embryogenesis can have significant consequences. By whatever causative factor, failure of the lateral maxillary process to fuse with the central globular process would be expected to result in a unilateral cleft of the upper lip. Similarly, the median cleft can be explained by incomplete merging of the median nasal processes and an oblique facial cleft by persistence of the groove between the maxillary and lateral nasal processes (medial canthal region to the ala of the nose).

Although it is understandable that some facial clefts occur when there is a lack of fusion of the various primordial facial processes, others are not readily explainable in such terms. A cleft that begins lateral to the philtrum and extends to the midportion of the lower eyelid is difficult to explain. As such, these atypical clefts, which are not obviously demarcated in the developing face, were considered ruptures of the embryonic tissue by external forces.

In the literature, differences of opinion exist regarding what fusion itself means in embryogenesis and what role cell proliferation, cell differentiation, cell degeneration, and the extracellular matrix play in morphogenesis.

MORPHOGENESIS OF FACIAL CLEFTING

Historically, two theories of facial clefting have been described: (1) the classic theory of fusion by Dursy⁵¹ and His⁵² and (2) the theory of mesodermal migration by Veau and Politzer,⁵³ Warbrick,⁵⁴ Stark,⁵⁵ and others. More recently, theories proposed by Johnston⁵⁶ and Vermeij-Keers et al⁵⁷ offered possible explanations of some of the more rare defects clinically seen.

Fig. 26-6 Development of the neural plate and origin of neural crest cells. Neural crest cells are believed to play a significant role, contributing to the mesenchyme of the craniofacial skeleton and connective tissue.

Proposed by Dursy in 1869⁵¹ and by His in 1892,⁵² the classic theory suggests that clefts develop because of a lack of fusion of the normally merging facial processes. After the free, bud-like ends of the facial processes establish ectodermal contact, mesodermal penetration occurs to complete the union. The upper lip is formed by the union of the frontonasal process centrally with the lateral maxillary processes. Disruption of the sequence—fusion followed by mesodermal penetration—leads to the various clefts of the upper lip.^{51,52}

In contrast to the classic theory, the theory of mesodermal migration emerged in the first half of the twentieth century. Its supporters believed that the free ends of the facial processes did not exist. Instead, the developing embryonic face was composed of a continuous bilamellar ectodermal membrane, with epithelial seams demarcating the various processes of the face. Within this bilamellar structure, mesenchyme migrates and penetrates to smooth out the seams.⁵⁸ Thus clefting seems to be related not to failure of fusion but to failure of mesenchymal migration. The facial processes as such do not fuse but rather merge.^{53,54,59}

Weston⁶⁰ and Johnston⁶¹ further refined the concept of mesodermal migration when they showed the importance of neural crest cells in the development of the mesodermal component of the craniofacial form. Their work identified a specialized group of cells, the *neuroectodermal cells*, arising from the dorsal lateral ectoderm of the neural fold to migrate extensively to their eventual destination along hyaluronate-rich, fibronectin-lined extracellular pathways.⁶² The cells play a significant role in contributing to the mesenchyme responsible for skeletal and connective tissue of the face (Fig. 26-6). The cells from the differing levels of the neural fold eventually populate specific regions: (1) cells from the prosencephalon and cranial mesencephalic levels of the neural tube populate the region of the frontonasal prominence, and (2) cells from the caudal mesencephalic and upper rhombencephalic region populate the primitive maxilla and developing mandible. This cranial-to-caudal sequence is preserved.^{63,64} If the migration is incomplete or insufficient in number or undergoes abnormal differentiation, various malformations then result. The severity depends on the stage at which the failure occurs. If mesodermal penetration and

differentiation by the neuroectodermal cells fail to occur, a facial cleft manifests as the epithelial seam breaks down.^{56,65}

More recently, studies by Vermeij-Keers et al⁵⁷ and others have shown migration of neural crest cells alone may not account for all varieties of facial clefting.⁶⁶ There is disagreement in the literature regarding whether the neural crest cells migrate or are developmental rests as the neural plate is transformed three dimensionally.^{56,62,64-68} Johnston's conclusions⁵⁶ of neural crest migration were based on nonmammalian vertebrate embryos. In contrast, studies based on murine embryos have failed to confirm the migration of neural crest cells relative to their surrounding mesenchyme. Instead, it appears that the neural crest cells are not moving alone through an extracellular matrix but are part of an integrated coordinated set of tissue displacements.^{63,67} Facial clefts then are not necessarily related to failure of migration but rather to failure of local differentiation of the neuroectoderm and mesenchyme.

Vermeij-Keers et al⁵⁷ identified four primary sites in early embryologic development that could lead to cleft formation between:

1. The junction of the medial and lateral nasal processes and maxillary process
2. The lateral nasal and maxillary processes
3. The maxillary and mandibular processes
4. The palatine processes

These sites are then the origins of true clefts, because they are associated with the normal planes of embryologic processes. All the defects arising at the site of the epithelial plate show an ectodermal defect. Closure of the ectoderm of the face occurs by the 17 mm crown-rump (CR) length stage, which is sometime within the seventh gestational week. Thereafter, within each facial element, differentiation of the mesenchyme into facial muscles and supporting bone and cartilaginous support occurs. Ossification centers arise to complete bone formation. If the ossification centers fail, then pseudoclefts develop. These are not true clefts, and as such, the terms *secondary cleft* or *dysplasia* were suggested by Vermeij-Keers et al⁵⁷ and van der Meulen et al.⁶⁹ Errors in early facial development, before the 17 mm CR stage, lead to true clefts; errors in the late embryonic stage, after the 17 mm CR stage, result in dysplasia or a pseudocleft. The location of the primary or true clefts is well defined. The clefts of the later embryonic stage of development depend not only on the well-defined set of membranous bones but also on the number and location of the ossification centers within each of the elements.⁴⁹ The atypical clefts are then believed to be accounted for by the variability in the number of ossification centers within each of the developing bony plates.⁶⁶ Sulik⁷⁰ has suggested that when human embryos at 5 and 6 weeks' gestation are carefully examined with scanning electron microscopy, the more familiar facial processes (nasal, maxillary, and mandibular) are composed of smaller units, representing possible growth centers. The boundaries between the growth centers can be correlated with the potential sites of atypical facial clefts⁷⁰ (Fig. 26-7).

Early in the development, when the brain and facial form are intimately connected, variable degrees of deficiency of the anterior neural plate lead to a series of malformations termed *holoprosencephaly*.⁷¹⁻⁷⁴ The name derives from when there is incomplete or complete failure of the anterior portion of the neural tube to form the cerebral hemispheres, resulting in a single (holo) forebrain (*prosencephalon*)⁷⁵ (Fig. 26-8). Such early failures before the third gestational week of embryogenesis also are associated with various monstrous facial dysmorphisms. If the prosencephalon and frontonasal process fail to develop, cyclopia, ethmocephaly, and cebocephaly can occur. In *cyclopia*, the most extreme form, there is a single median eye or closely approximated paired ocular structures (*synophthalmia*) in a single orbit associated with arhinia and a rudimentary proboscis above the ocular field. In *ethmocephaly*, the hypoteloric eyes are structurally separate with an intervening proboscis. In *cebocephaly*, the ocular hypotelorism is to a lesser degree, and the proboscis is below the ocular field and more closely resembles a rudimentary nose with a blind single nostril.⁷⁶

Fig. 26-7 Embryonic lines superimposed on an embryo at 6 weeks' gestation. The potential clefts are numbered according to Tessier's classification from 0 to 14, along with the mandibular midline Tessier 30 cleft. Although not formally identified in Tessier's classification, the paramedian cleft is noted as Tessier 29/28 at the junction of the two mandibular prominences. (*Md*, Mandible; *Mx*, maxilla; *T30*, Tessier 30 cleft.)

Fig. 26-8 Holoprosencephaly. The prosencephalon fails to cleave sagittally into cerebral hemispheres. Convergence of the optic and olfactory placodes results in failure of development of the embryonic brain and frontonasal process.

In contrast, median facial defects characterized by orbital hypertelorism are believed to occur late, after the 17 mm CR stage. The ocular complex remains in the lateral position as a result of the intervening frontonasal process arrested in the low embryonic position. Normally, the internasal groove disappears with the forward growth (frontocaudal direction) of the nasal septum and simultaneously the distance between the ocular complexes decreases. When this fails, orbital hypertelorism occurs, wherein both distances between the medial orbital and lateral orbital walls are increased.⁷⁷

There is an extensive body of literature in which the typical clefts and various atypical clefts can be related to fundamental embryologic processes based on more recent concepts of neuromeric organization. The embryonic brain and spinal cord are divided into functional segments along the neuraxis that resemble a string of pearls. These units are called *neuromeres*. The forebrain, or prosencephalon, contains six prosomeres. Prosomeres 1 through 3 and 4 through 6 constitute the primitive diencephalon and telencephalon, respectively. The midbrain, or mesencephalon, is derived from *mesomeres* 1 and 2. *Rhombomeres* 0 through 11 constitute the primitive hindbrain, or *rhombencephalon*. Each neuromere proceeding caudally from the hindbrain is flanked by a *somitomere*, which subsequently differentiates into formed structures. Pertinent to facial anatomy, the first seven somitomeres form the cranial base dorsally and the first three pharyngeal arches ventrally. The fourth through the sixth pharyngeal arches are formed by the ventral mesoderm of somitomeres 8 through 10. The morphology of the face is produced by the assembly of embryonic fields according to a genetic program. Fields represent true neuroangiosomes that move analogously to tectonic plates, whereas processes merely represent the topography of the embryonic face. Clefting is believed to result from the mechanical disruption of programmed field interactions. Carstens⁷⁸ details the contemporary view of head and neck embryology, which is relevant to the plastic surgeon who treats congenital deformities.⁷⁹

CLASSIFYING THE RARE CRANIOFACIAL CLEFT

Classification of Median Facial Anomalies

The *median cerebrofacial malformations* are developmental anomalies of the midline brain and facial structures. Unlike the oblique facial clefts, the median facial defects can more readily be understood on an embryologic basis and consequently are easier to classify. As a group of midline deformities, these can be broadly subdivided into (1) those involving a deficiency in tissue and (2) those involving either an excess or near-normal amount of intervening tissue. However, extremes of malformation in both groups represent opposite ends of a continuous spectrum of median facial anomalies.

Tissue-Deficient Median Cerebrofacial Dysmorphogenesis

In an attempt to categorize cases of median facial anomalies in which there is deficient central cerebral/facial tissue, in 1963 DeMyer and Zeman⁷⁵ proposed the term *holoprosencephaly*. The prosencephalon remains “holistic,” failing to cleave sagittally into the cerebral hemispheres, transversely into the telencephalon and diencephalon, or horizontally into olfactory and optic bulbs. These cases can be graded to the degree of severity as to lobar, semilobar, and alobar holoprosencephaly (Fig. 26-9). Embryologically, an intimate relationship exists between the developing midfacial structures and forebrain, and as such, the degree of facial disorganization reflects an equally severe anomaly of the brain.^{71,80} The varying degrees of facial dysmorphism associated with the severity of holoprosencephaly have been grouped into five major types^{72,77,80} (Table 26-2):

- I. Cycopia
- II. Ethmocephaly
- III. Cebocephaly
- IV. Hypotelorism with median cleft lip
- V. Hypotelorism with bilateral cleft lip

Table 26-2 Holoprosencephaly

Type/Group	Facial Morphology	Brain Morphology
I Cyclopia	Monophthalmia, synophthalmia, or anophthalmia Proboscis (single/double), arhinia	Alobar
II Ethmocephaly	Extreme hypotelorism Proboscis (single/double), arhinia	Alobar
III Cebocephaly	Hypotelorism Proboscis-type nose (blind end/single nostril)	Alobar
IV	Hypotelorism Flat nose Median cleft lip	Alobar (usually)
V	Hypotelorism Flat nose Bilateral cleft lip	Semilobar or lobar

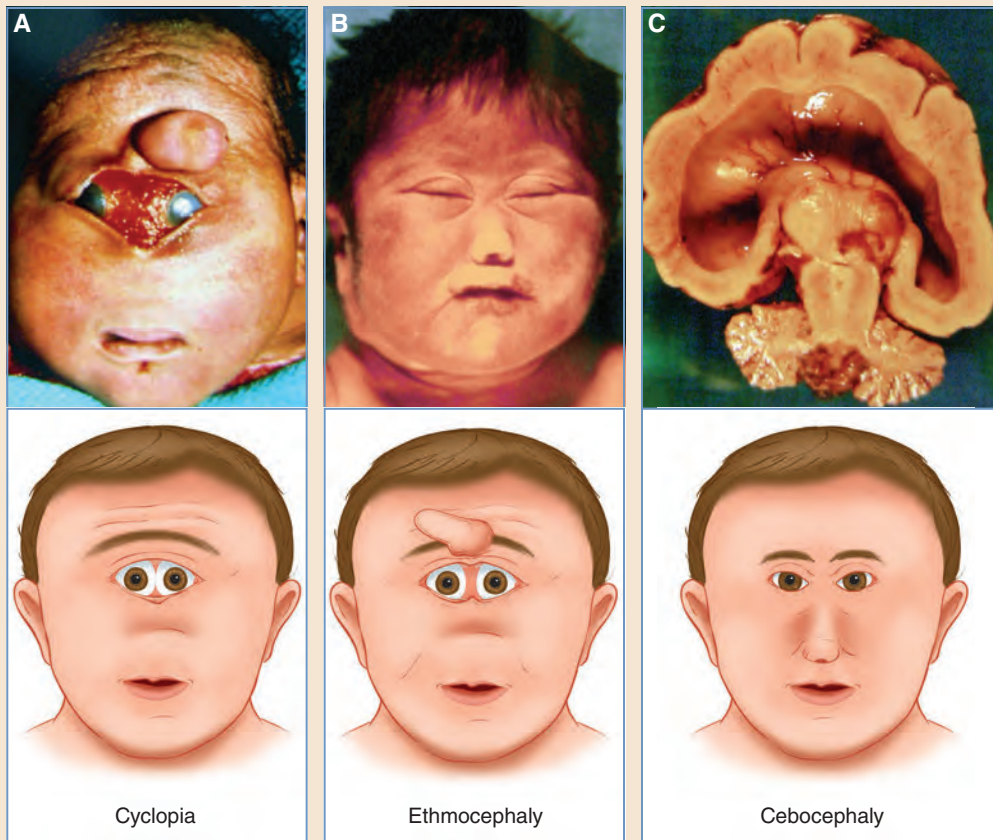

Fig. 26-9 Spectrum of facial dysmorphism associated with alobar holoprosencephaly. **A**, Cyclopia. **B**, Ethmocephaly. **C**, Cebocephaly.

The degree of correlation between the brain and face is not absolute. The predictive correlation is only about 80%.^{81,82} For the clinician deciding which infant may be a candidate for reconstruction, the distinction between the groups becomes clinically relevant. Infants who fall into types I, II, or III, in which the brain morphology is alobar, rarely survive beyond the first year of life and are not candidates for reconstruction. The difficulty lies in determining which infants in the type IV and V categories should be offered reconstructive surgery. The classification scheme of DeMyer et al,⁸⁰ which was later modified by Cohen et al,⁷² Cohen and Sulik,⁷⁶ and Cohen⁸³ is based primarily on the cleavage of the brain. There remains a wide spectrum of midfacial hypoplasia and false median clefts that can occur in the absence of any significant brain pathology.⁸⁴⁻⁸⁹ These last two categories are more usefully further stratified based on prognostic and functional criteria in the proposed reclassification of Elias et al⁹⁰ (Table 26-3).

In the revised scheme, *types I* through *III* remain unchanged, because they all reflect alobar holoprosencephaly. *Type IV* as a transition includes either alobar or semilobar holoprosencephaly, and *Type V* includes lobar holoprosencephaly. *Type VI* would be added to represent normal brain development, and yet facial dysmorphogenesis is consistent with the characteristics of this group of deformities. *Type VI* can be further subdivided based on the presence or absence of a false median cleft lip. Despite similarities in dysmorphic facial appearance, *type VI* cannot be considered a true holoprosencephaly, because the brain is anatomically normal. Our experience has been that infants with revised *types V* and *VI* facial deformity should be given the opportunity of surgical reconstruction. Although infants in type V are invariably mentally deficient, their potential for life expectancy justifies early repair of the lip and palate. Similarly, infants in *group VIa* should undergo early lip and palate repair. Unlike *type V* infants, a further major craniofacial procedure should be contemplated with *type VI* deformities, with the understanding that subtle neurologic deficits may exist.⁹⁰

Table 26-3 Median Cerebrofacial Dysmorphogenesis

Type/Group	Facial Morphology	Brain Morphology		Operative Procedure
I Cyclopia	Monophthalmia, synophthalmia, anophthalmia Proboscis (single/double), arhinia	Alobar	HOLOPROSENCEPHALY	None
II Ethmocephaly	Extreme hypotelorism Proboscis (single/double), arhinia	Alobar		None
III Cebocephaly	Hypotelorism Proboscis type nose (blind end/single nostril)	Alobar		None
IV	Hypotelorism Flat nose False median cleft lip	Alobar/semilobar		None
V	Hypotelorism Flat nose False median cleft lip	Lobar		Lip/palate repair only
VI	Hypotelorism Flat nose	Normal		Lip/palate repair LeFort III
VIa	False median cleft lip			Facial bipartition
VIb	No false median cleft lip			

Tissue Excess or Near-Normal Median Cerebrofacial Dysmorphogenesis

DeMyer⁹¹ proposed the term *median cleft face syndrome* to describe this collection of median facial anomalies characterized by near-normal or excess tissue. The dysmorphic features can vary from a subtle midline notch of the upper lip to an obvious bifidity of the nose, and in more severe cases hypertelorism (Fig. 26-10). Characteristic features of the syndrome include:

- Orbital hypertelorism
- V-shaped frontal hairline
- Bifid cranium
- Median cleft of the upper lip
- Median cleft of the premaxilla
- Median cleft of the palate
- Primary telecanthus

Unlike holoprosencephaly, there is little predictive value between the face and underlying brain. The likelihood of mental retardation increases in patients with severe hypertelorism or if it is combined with extracephalic deformities.⁹¹

Instead, Sedano et al⁹² preferred the term *frontonasal dysplasia* and first suggested that this group of midline defects likely represents the opposite end of the spectrum from holoprosencephaly. Their preference for the term frontonasal dysplasia is objectionable. The term neither accurately describes the median nature of these defects nor does it seemingly include median labial-palatal defects. The term is vague as it has been used in the literature. Moreover, it has included nasal alar clefts that are not true midline defects. DeMyer's⁹¹ more preferable term emphasizes the median nature of this group of anomalies but is also objectionable, because it implies a syndromic feature to these defects. We prefer instead the term *median cleft face dysmorphism* to describe this category.

DeMyer's inclusion of primary telecanthus⁹¹ as a characteristic should also be dropped, because it is not a true midline defect. *Primary telecanthus* more accurately describes the lateral displacement of the medial canthi as seen in blepharophimosis. *Hypertelorism* emphasizes the skeletal deformity, in which there is an increased distance between the medial orbital walls. Although hypertelorism is a characteristic physical finding in this group of midline facial clefts, paramedian clefts can also result in hypertelorism.^{9,10}

Fig. 26-10 Median cleft face dysmorphism with central tissue excess represents the opposite end of the spectrum from holoprosencephaly.

Classification of Oblique Clefts

For decades the task of classifying rare oblique craniofacial clefts has posed a challenge. Since the numerous early attempts at classification by Morian in 1887,⁹³ Sanvenero-Rosselli in 1953,⁹⁴ Burian in 1960,⁹⁵ Lund in 1966,⁹⁶ the rare or atypical clefts have seemed to defy any simple and obvious classification. The clefts are rare, the descriptions in the literature are incomplete, and the definitions are not necessarily agreed on. In more recent years, several different classifications have been proposed, but none have gained absolute universal acceptance by all investigators. The proposed classification schemes have been based purely on either observed anatomic lines without regard to any underlying causative principles (for example, by Boo-Chai,⁹⁷ Tessier,⁹⁸ and Harkins et al⁹⁹) or on an understanding of embryologic studies (for example, Karfik¹⁰⁰ and Van der Meulen et al⁶⁹). The basic scientist prefers an embryologic classification, whereas the clinician prefers simplicity with clinical applicability.

In 1962 the American Association of Cleft Palate Rehabilitation⁹⁷ classified the rare facial clefts into four major groups: (1) mandibular process clefts, (2) nasoocular clefts, (3) oroocular clefts, and (4) oroaural clefts (Fig. 26-11). The oroocular clefts were further subdivided into oral medial canthus and oral lateral canthus clefts with a temporal extension. The midfacial defects and clefts related to Treacher Collins syndrome were omitted in this classification. Moreover, because it was based only on surface anatomy, this simple classification scheme failed to consider the underlying skeletal pathology.

In 1970 Boo-Chai,⁹⁷ who recognized Morian's initial observations from 1887,⁹³ subdivided the oroocular clefts more specifically into two types: *Type I clefts* began just lateral to the philtral ridge and continued in a cephalic direction to end in the region of the medial canthus. Its skeletal counterpart began between the lateral incisor and canine, coursing medial to the inferior orbital foramen, and on to the inferior medial aspect of the orbit. In contrast, *type II clefts* began more laterally near the oral commissure and ended either at the midportion of the eyelid or lateral

Fig. 26-11 Classification scheme endorsed by the American Association of Cleft Palate Rehabilitation in 1962. The clefts were broadly classified into one of four major categories: mandibular, nasoocular, oroocular, and oroaural.

Fig. 26-12 Classification scheme proposed by Boo-Chai in 1970 for oroocular clefts. The clefts are divided according to whether they course medial (type I) or lateral (type II) to the infraorbital nerve.

canthus. The skeletal cleft began in the premolar region, coursed lateral to the inferior orbital foramen, and terminated at the inferior lateral orbit (Fig. 26-12).

In contrast to the above attempts at a phenomenologic classification of clefts, in 1966 Karfik¹⁰⁰ presented a classification based on embryologic and morphologic grounds (Box 26-1). The cleft malformations were divided into five major groups¹⁰⁰:

1. Rhinencephalic disorders
2. Branchiogenic disorders
3. Ophthalmoorbital disorders
4. Craniocephalic disorders
5. Atypical facial disorders

Unfortunately, the oroocular clefts could not be clearly categorized. Group A includes not only the nasoocular clefts but also the oroocular clefts of type I described by Boo-Chai⁹⁷ and Morian,⁹³ which do not have nasal involvement and start lateral to the common cleft lip. Type II oroocular clefts were grouped in group E under atypical facial disorders, along with facial asymmetries, neoplasms, and others that could not be explained by an embryologic seam. Moreover, Apert and Crouzon syndromes are included in group D, which today would be considered dysostosis rather than a clefting phenomenon.

Box 26-1 Facial Cleft According to Karfik**Group A: Rhinencephalic Disorders*****A1, Axial***

Prolapse: Meningocele, glioma, dermoid cyst, teratoma

Clefts: Medial nasal (double nose), median cleft of the upper lip and premaxilla

Defects: Coloboma of nostril, partial nose, total nose, septal, atresia nasi

A2, Paraaxial Clefts

Coloboma, iris or palpebral, total or partial paraaxial cleft lip, typical, lacrimal duct dystopia

Group B: Branchiogenic Disorders***B1, Lateral Otocephalic***

Clefts: Macrostomia, lateral cervical fistula

Dysostosis: Mandibular (for example, Pierre Robin sequence), mandibulofacial (for example, Treacher Collins syndrome)

Defects: Partial or total auricular, atresia

B2, Median Axial Clefts

Tongue, lower lip, mandible, fissura colli medialis, fissura thoracis medialis

Group C: Ophthalmoorbital Disorders

Malformations: Eyeball: microphthalmia, anophthalmia; lids: Blepharophimosis, epicanthus

Defects: Orbital

Group D: Craniocephalic Disorders

Malformations: Head and face (for example, Apert syndrome, Crouzon disease)

Defects: Scalp, skull

Group E: Atypical Facial Disorders

Oblique facial cleft, parasitic dysembryoma, hemifacial atrophy, hyperplasia, congenital neoplasm, teratoma

Subsequently, in 1983, Vermeij-Keers et al⁵⁷ proposed a classification scheme based on the embryologic work of van der Meulen⁶⁹ (Box 26-2). As previously discussed, van der Meulen et al⁶⁹ showed that the underlying pathologic findings of the malformations can be interpreted as developmental arrests that occurred either before the fusion of the facial processes (17 mm CR stage of the embryo) or after—during the differentiation phase. The early defects result in true clefts, or primary clefts, along embryologic processes. The late defects, caused by errors in differentiation and fusion of ossification centers, result in pseudoclefts, or secondary clefts.⁶⁶

Objecting to the use of the term *cleft*, Vermeij-Keers et al⁵⁷ proposed that the more general term *dysplasia* would be more applicable, because the defects seen do not necessarily represent obvious clefts, depending on the severity of involvement. Both true clefts (for example, cleft lip and palate) and pseudoclefts (Treacher Collins syndrome and hemifacial microsomia) would be regarded as dysplasia in the classification scheme.⁶⁹ Moreover, the dysplasia should be properly identified by the area of the facial processes involved rather than assigned a random numeric classification. Furthermore, a distinction should be made between malformations of the face and cranium alone (*craniofacial dysplasia*) and craniofacial defects involving the brain (*cerebrofacial dysplasia*), which occur earlier in the embryologic development. Craniofacial dysplasia is further

Box 26-2 Classification of Craniofacial Malformations According to van der Meulen et al

- I. Cerebrocranial Dysplasias
- II. Cerebrofacial Dysplasias
 - A. Rhinencephalic dysplasias
 - B. Oculoorbital dysplasias
- III. Craniofacial Dysplasias
 - A. With clefting
 - 1. Lateronasomaxillary cleft
 - 2. Medionasomaxillary cleft
 - 3. Intermaxillary cleft
 - 4. Maxillomandibular cleft
 - B. With dysostosis
 - 1. Sphenoidal
 - 2. Sphenofrontal
 - 3. Frontal
 - 4. Frontofrontal
 - 5. Frontoethmoidal
 - 6. Internasal
 - 7. Nasal
 - 8. Premaxillomaxillary and intermaxillopalatine
 - 9. Maxillozygomatic
 - 10. Zygomatic
 - 11. Zygoauromandibular
 - 12. Temporoaural
 - 13. Temporoauromandibular
 - 14. Mandibular
 - 15. Intermandibular
 - C. With synostosis
 - 1. Craniosynostosis
 - 2. Craniofaciosynostosis
 - 3. Faciosynostosis
 - D. With dysostosis and synostosis
 - E. With dyschondrosis
- IV. Craniofacial Dysplasia With Other Origin

subdivided by dysplasias with clefting, dysostosis, and synostosis. For example, the type II oblique cleft of Boo-Chai⁹⁷ is replaced by the lateronasomaxillary cleft under the group of craniofacial dysplasias and holoprosencephaly and by rhinencephalic dysplasia in the group of cerebrofacial dysplasias.

Unfortunately, the terms dysplasia, dysostoses, and synostoses, used in the scheme, are not well defined. The accepted meaning of the term dysplasia now refers to generalized disorders of skeletal involvement, and the term dysostosis refers to involvement of a few regional bones (International Nomenclature of Constitutional Diseases of Bone). The value of replacing the term *mandibulofacial dysostosis* (Treacher Collins syndrome) with *zygomaticotemporoauromandibular dysplasia* is unclear.^{10,101}

Nevertheless, a classification scheme, including both descriptive terminology and insights into the underlying embryologic cause, would be preferable. However, Tessier's simplistic classification, despite its disregard for any embryologic or pathologic sequence, remains the most useful and widely accepted classification scheme today.

TESSIER CLASSIFICATION

In 1974 at the Interdisciplinary Workshop Conference in Chicago on Craniofacial Surgery, Tessier^{98,102} presented a comprehensive classification scheme of craniofacial clefts based on personal experience with 336 patients. Detailed descriptions were then later published in 1976 by Tessier^{98,102} and Kawamoto.⁹

Tessier's system^{9,10,98,102} represents an architectural description of defects rather than offering true descriptions of the structures involved. The defects are numbered for ease of clinical classification rather than along any pathoembryogenic sequence. Although it fails to provide insight into the underlying etiopathology of these defects, the relative simplicity of his classification has made it almost universally accepted for clinical use. The classification has significant value to the practicing reconstructive surgeon, because it is based not only on careful physical examination and radiologic studies, but also correlated with anatomic findings at the time of surgery.

Tessier^{9,10,98,102} noted that the important landmarks through which the fault lines cross are the mouth, nose, orbit, and cranium and found that 15 distinct cleft locations can be differentiated. The clefts are numbered from 0 to 14, in a counterclockwise fashion, circumferentially around the orbit, along constant planes (Figs. 26-13 through 26-16). The orbit was selected as the point

Fig. 26-13 Tessier proposed a comprehensive architectural classification of atypical clefts in 1974. The clefts are centered on the orbit and are numbered from 0 to 14. The soft tissue clefts are correlated with the corresponding skeletal fault lines. (Courtesy of Paul Tessier, MD.)

Fig. 26-14 Detail of the clefts involving the upper lip and nostril and the corresponding anterior dentoalveolar clefts. Clefts 1, 2, and 3 have their common origin at the Cupid's bow peak and correspond to the more prevalently seen cleft lip deformity. Beginning with the number 4 cleft, the ala and piriform aperture are spared. (Courtesy of Paul Tessier, MD.)

Fig. 26-15 Detail of clefts involving the posterior dentoalveolar region. The number 5 cleft originates in the premolar region. A cleft of the posterior maxillary alveolus is occasionally seen with the number 7 cleft. In contrast, a cleft, per se, is not seen with the number 6 cleft but instead an area of alveolar hypoplasia. (Courtesy of Paul Tessier, MD.)

Fig. 26-16 Detail of clefts involving the orbital region. The course of the clefts is shown in relation to the eyelids and eyebrow, along with the corresponding involvement of the underlying orbital skeleton. (Courtesy of Paul Tessier, MD.)

of reference, because it belongs to both the cranium and face. These planes then divide either the cranium or face, depending on the direction the cleft takes from the orbit or palpebral fissure. Southbound clefts pass caudally from the orbit and become purely facial clefts, and northbound clefts passing cephalad from the orbit become cranial clefts.^{9,10,98,102}

Cranial (northbound) and facial (southbound) clefts frequently coexist, and when they do, their axes usually (although not always) follow the same general direction. Such craniofacial clefts are then numbered by their component parts. For example, facial cleft number 0 is seen with its cranial component 14; similarly, combinations of clefts 1 through 13, 2 through 12, 3 through 11, 4 through 10, and 5 through 9 are clinically observed. The combinations of cranial and facial (craniofacial) clefts usually add up to 14. Combinations of purely facial clefts also exist. Treacher Collins syndrome is a combination of clefts 6, 7, and 8.^{9,10,98,102}

Tessier's numeric system is purely a topographic map of the cleft fault lines. It describes neither the specific structures involved nor the degree of involvement of each of the structures. The face can be marred by both a mild crease in the skin or a subtle change in the contour of the hairline to a frank expression of the cleft (Figs. 26-17 and 26-18). Both are described by the same

Fig. 26-17 Disruption of hairlines is often seen with the cranial extension of the clefts, and as a subtle finding, they may suggest the course of the cleft. (Courtesy of J.M. Converse, MD.)

Fig. 26-18 Clefts do not need to be expressed fully and may be marked only by subtle soft tissue disruptions. **A**, An alar notch suggests a number 1 cleft. **B**, Colobomas and dystopia of the medial and central eyelashes and eyebrow suggest a number 10 cleft.

number in the classification. For example, a number 7 cleft describes a situation in which there is only a transverse cleft of the oral commissure, resulting in macrostomia. It also describes a more complete form in which all structures along its path, both soft tissue and skeletal, are involved, resulting in the typical features of hemifacial microsomia.^{9,10}

The value of Tessier's classification scheme is that it directs the clinician to search for the malformations along the entire axis. The structures that may be involved in a particular cleft are then inferred from the path that the cleft takes. For example, without careful examination of the cephalic structures of the common cleft lip, malformations of a more complex cleft can be missed. Both the common cleft lip and the labial cleft of Tessier's facial cleft numbers 1, 2, and 3 begin in the region of the Cupid's bow. The cranial or northbound clefts not previously suspected may be revealed by subtle irregularities of the anterior hairline.^{9,10,103}

In Tessier's original line drawings,⁹⁸ both clefts 2 and 9 were drawn with dotted lines. Both clefts were notably rare. Tessier based the axis of the number 9 cleft on cases reported by Morian⁹³ and Sanvenereo-Rosselli,⁹⁴ and Tessier was unsure whether cleft 2 represented a distinct entity. Since the original descriptions, the clefts have been identified in the literature.^{8,104-107}

Description of Facial Clefts

Although the upcoming section describes the individual clefts, there are general rules of thumb that will be helpful. Table 26-4 summarizes the comparative anatomy of the Tessier cleft pattern. Clefts 0, 1, and 2 course medial to the canthus, and as such, do not directly pass through or disrupt the orbit. Clefts 1, 2, and 3 begin at the Cupid's bow, as does the common cleft lip. The distinguishing features are then markedly more cephalic in the nasal region. Cleft 1 has a characteristic notch of the alar dome, and cleft 3 undermines the alar base in its course to involve the orbit. The upper lip cleft of 4 begins lateral to the philtrum, and cleft 5 begins just medial to the commissure. Neither cleft 4 nor 5 directly involves the piriform aperture or the nasal structures. Clefts 3 and 4 enter the palpebral fissure medial to the inferior punctum of the canalicular system, and as such, disrupt the normal anatomy of the medial canthal region. Cleft 5 enters lateral to the punctum, and the medial canthus is not directly involved. Cleft 4 courses medial to the inferior orbital foramen, and cleft 5 courses lateral to the foramen. Cleft 6 has no labial component and is purely an orbital cleft, whereas cleft 7 has no orbital component and labially is a transverse cleft, originating from the oral commissure. Cleft 8 originates as a transverse cleft from the lateral commissure of the palpebral fissure. Beginning with the number 9 cleft, the cleft becomes cranial or northbound. Clefts 9, 10, and 11 disrupt the upper eyelid and eyebrow. Clefts 10 and 11 can result in orbital dystopia because of direct involvement of the orbit. Clefts 12, 13, and 14 course medial to the orbit and result in hypertelorism.

From the midline to the inferior orbital foramen, the clefts of the soft tissue are more frequent and more disruptive than those of the underlying skeleton. In contrast, from the foramen laterally, the defects in the bony structures are typically more involved than those of the soft tissue. Two notable exceptions are the more frequent soft tissue auricular involvement of the number 7 cleft and the more significant skeletal disruption of the number 3 cleft that can occur.

The most common cleft types seen are the median clefts 0 and 14, although the transverse cleft, number 7, would be expected to be significantly more common with a stricter definition. The least frequently encountered are oblique cleft numbers 4, 5, 8, and 9 of the atypical clefts. In contrast, paramedian clefts are encountered more often than oblique clefts.

Table 26-4 Comparative Anatomy of Atypical Craniofacial Clefts

Cleft Type	Lip Alveolus	Nasal Region Piriform Aperture	Cheek Maxilla/ Zygoma	Orbital Level	Supraorbital/Cranium	Cleft Type
0	True median cleft Between central incisors	Bifid nose Septum thick, duplicated	— —	— Nasal bones hyperplastic Ethmoid labyrinth Hypertelorism	Flattened frontal region or median encephalocele Bifid cranium Crista galli widened, duplicated Distance between olfactory grooves increased Ethmoid labyrinth	14
1	Cupid's bow Between central/lateral incisors	Alar dome notch Piriform aperture lateral to anterior nasal spine	— —	— Nasal bone Ethmoid labyrinth Hypertelorism	Dystopia of the medial edge of brow Paramedian encephalocele Widened olfactory groove/cribriform plate Ethmoid labyrinth	13
2	Cupid's bow Region of lateral incisor	Middle third alar rim Lateral piriform aperture	— —	— Nasal bone/frontal process of maxilla Ethmoid labyrinth Hypertelorism	Disrupts medial third of brow Upper eyelid uninvolved Lateral to the cribriform plate Ethmoid labyrinth	12
3	Cupid's bow Between lateral incisor/cuspid	Alar base Junction of lateral nasal wall/floor	Lateral nasal-cheek junction Loss of normal bony septation between the nasal/maxillary cavity	Medial canthus disrupted Lower eyelid defect medial to the punctum Lacrimal system disrupted 1. Frontal process of the maxilla Ethmoid labyrinth Hypertelorism 2. Lateral to the ethmoid bone	Medial third of upper eyelid Medial third of the eyebrow 1. Lateral to the cribriform plate Ethmoid labyrinth or 2. Medial third of the supraorbital rim	11
4	Midway between philtrum and commissure Between lateral incisor/cuspid	— —	Medial cheek Anterior maxillary wall medial to the infraorbital foramen	Lower eyelid medial to the punctum Lacrimal system except for inferior canaliculus is spared Inferomedial orbital rim and floor	Middle third of upper eyelid Middle third of eyebrow Middle third of the supraorbital rim	10
5	Medial to the commissure Distal to the cuspid in the premolar region	— —	Lateral cheek Anterior maxillary wall lateral to the infraorbital foramen	Medial and lateral third of the lower eyelid Middle third of the orbital rim and floor	Lateral third of upper eyelid Lateral third of eyebrow Superolateral orbital rim	9
7	Oral commissure Incomplete cleft molar region	— —	Lateral cheek to the ear Zygomatic arch Mandible	Medial and lateral third of the eyelid Antimongoloid slant palpebral fissure Zygomaticomaxillary suture	Lateral canthus Frontozygomatic suture	8
Cleft Type	7			6	8	Cleft Type

NOTE: Clefts 0-14 include "median hypoplasia" (holoprosencephaly), not included in the above table.

Based on Tessier's classification, the most reliable figures in the distribution of the types of clefts come from the large data collected by Ortiz-Monasterio and Taylor⁸ (Table 26-5). In their series, cleft 0 accounted for 17% of the cases, cleft 7 for 15% of the cases, and cleft 14 for 12% of the cases. The least common atypical clefts reported were the number 5 and 9 clefts (<1%). Moreover, craniofacial clefts do not necessarily occur as isolated clefts and are frequently combined with other clefts (Table 26-6).

Table 26-5 Atypical Craniofacial Clefts

Tessier Number	Presenting as Single Cleft	Presenting as Multiple Clefts	Total (N = 998)	Percentage of Total
0	40	132	172	17.2
1	5	81	86	8.6
2	14	47	61	6.1
3	20	48	68	6.8
4	12	26	38	3.8
5	3	5	8	0.8
6	2	57	59	5.9
7	58	89	147	14.7
8	6	58	64	6.4
9	—	5	5	0.5
10	3	17	20	2.0
11	2	22	24	2.4
12	1	37	38	3.8
13	2	81	83	8.3
14	3	121	124	12.4

Series of 998 clefts in 495 patients between 1965 and 2006.

Table 26-6 Incidence of Atypical Multiple Cleft Pattern

Tessier Number	Number of Multiple Presentations	Percentage of Multiple Presentations	Percentage of Total Clefts
0-14	115	35.7	11.5
0-13	3	0.9	0.3
1-13	71	22.0	7.1
2-12	31	9.6	3.1
3-11	10	3.1	1.0
3-12	1	0.3	0.1

Various	39	12	3.9

Fig. 26-19 Clefts do not necessarily occur in a pure isolated form. They may present as unilateral, bilateral, or as a combination of individual clefts. Clinical description of the cleft pattern requires numbering the individual clefts, noting right (*R*) side and left (*L*) side involvement. **A**, Unilateral right number 4 cleft, 4R. **B**, Bilateral number 3 cleft, 3R-3L. **C**, Number 7R.1R.13R.0-14.12L.2L.7L. However, for a complex cleft, it can be difficult to delineate each of the Tessier clefts that are in close juxtaposition.

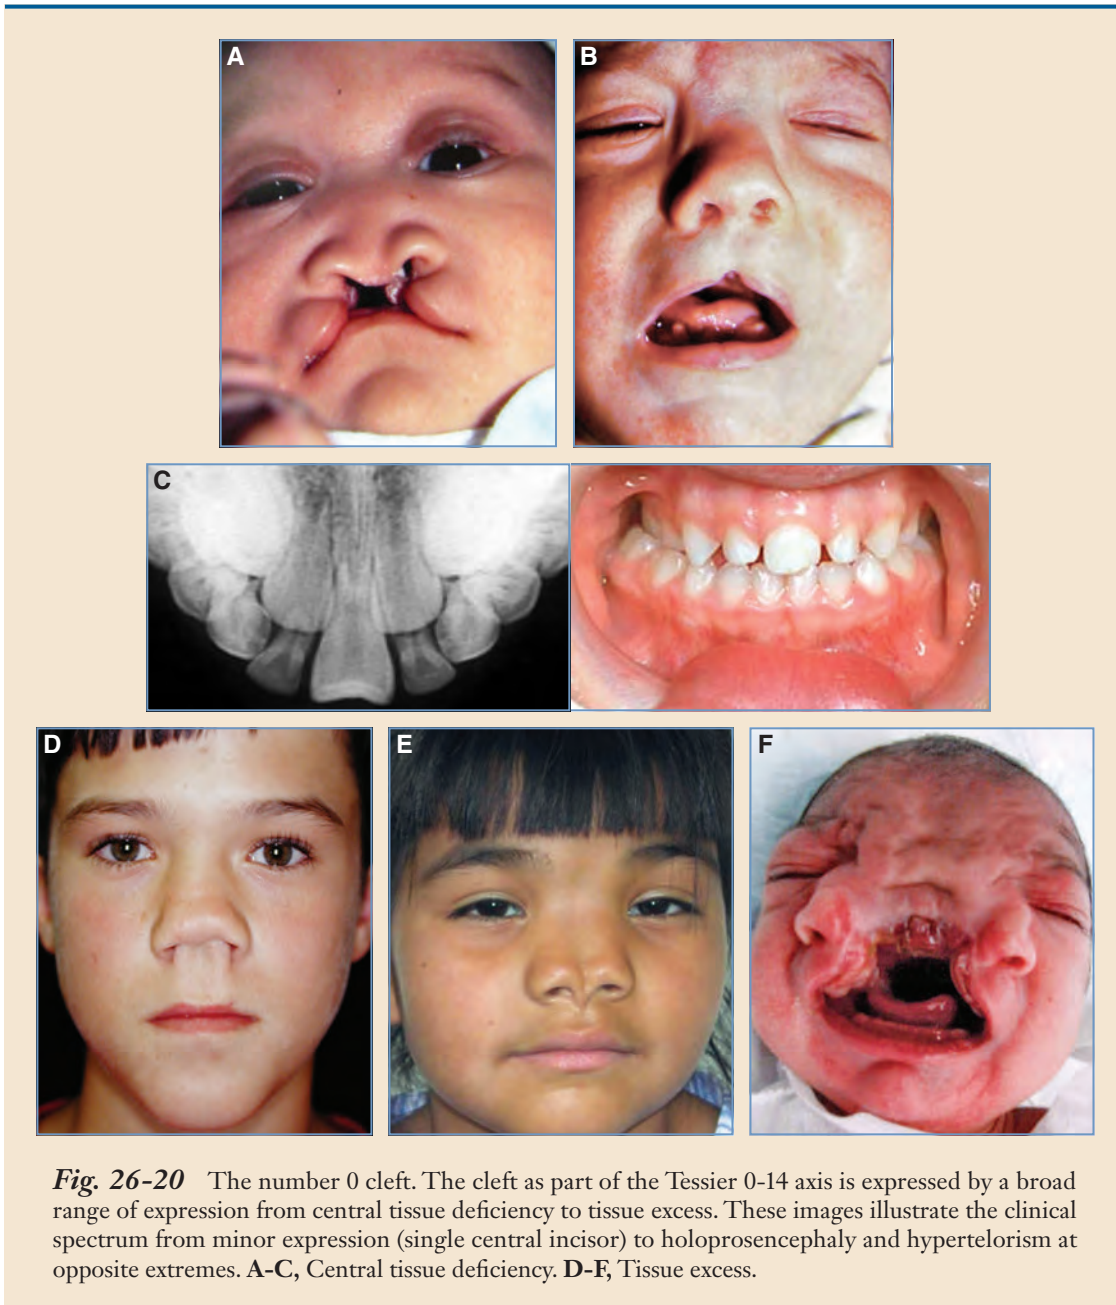

The clinical presentation of a cleft pattern may be considered as a combination of separately numbered elements of the Tessier system (Fig. 26-19). The most common combination was 0-14 (36%), followed by 1-13 (22%) and the 6-7-8 combination (16%).

Unilateral and bilateral clefts can be found in varying combinations (see Fig. 26-19). In their series of 495 patients, the atypical cleft was unilateral in 164 patients (33%) and bilateral in the remaining 331 (67%) of patients. When clefts are bilateral they are frequently symmetrical with respect to their axis, but not necessarily in the severity of their involvement. Nearly one half of the cases of clefts 1 and 2 present as bilateral clefts. In contrast, the more oblique clefts 3, 4, and 5 present less frequently, between 20% and 30%, as bilateral clefts.^{8,10}

Number 0 Cleft

The number 0 cleft is in the midline of the face (Fig. 26-20). Along with its cranial extension, the number 14 cleft, it is a median craniofacial dysraphia and includes the median cleft face dysmorphism (hyperplasia) and holoprosencephaly (hypoplasia). The 0-14 axis can be further classified along the lines previously discussed.

The cleft of the upper lip varies from a minor vermilion notch to a true median cleft. The frenulum is often duplicated, and there is a diastema between the maxillary central incisors. The nose is frequently bifid, and the columella and dorsum of the nose are wide and often associated with a median furrow. Its skeletal course follows a midline path. The bony cleft begins in the alveolus between the central incisors. The dentoalveolar arch is angulated upward into the cleft.

Posteriorly, the cleft may continue in the midline of the premaxilla through the secondary palate. Superiorly, the anterior nasal spine and septum may be either thickened or duplicated. The lower and upper lateral cartilages of the nose are displaced laterally and may be hypoplastic or distorted. The nasal bones are wide and flattened. The anterior ethmoid cells are increased in number and enlarged (posterior ethmoid and sphenoid are typically uninvolved), resulting in hypertelorism.*

*References 9, 10, 91, 98, 102, 104, 108-113.

Fig. 26-21 The number 1 cleft. The characteristic finding of the cleft is notching of the ala dome. The cleft begins in the region of the lateral and central incisors and courses through the nasal floor and superiorly through the nasal bones. The cleft continues cranially as a number 13 cleft.

At the other end of the spectrum, the number 0 cleft may have the hypoplastic features of holoprosencephaly. A false median cleft of the lip is seen with partial or total absence of the proboscis. The nose may be rudimentary, absent (arhinia), or merely a proboscis. The midline bony defect results in either partial or complete absence of the premaxilla. A cleft of the secondary palate is often seen. The septum, if present, is vestigial. The osteocartilaginous portion of the nasal vault may be hypoplastic or entirely absent. Superiorly, the bony defect continues as a number 14 cleft into the ethmoid, resulting in hypotelorism.*

Number 1 Cleft

The Tessier number 1 cleft begins in the region of the Cupid's bow, continues northbound to involve the alar dome of the nostril, and extends onto the nasal dorsum. Although telecanthus has been described, the fault passes well medial to the canthal structures, which are normal (Fig. 26-21).

The skeletal course of the cleft passes through the alveolus between the central and lateral incisors, through the base of the piriform aperture, just lateral to the anterior nasal spine without involving the septum directly. The cleft of the maxilla may extend posteriorly to form a complete cleft of the hard and soft palates. Superiorly, the fault continues through the nasal bone medial to its junction with the frontal process of the maxilla. Hypertelorism results as the fault courses parasagittally toward the glabella-forehead region to involve the ethmoidal labyrinth. It continues as a Tessier number 13 cleft with involvement of the cranium. The combination 1-13 cleft is a paramedian craniofacial cleft.^{9,10,98,102,104}

*References 9, 10, 82, 98, 102, 104, 114-116.

Fig. 26-22 The number 2 cleft. A characteristic of the cleft is that the alar rim appears hypoplastic and is drawn upward. A true notch, per se, of the alar rim is not seen. The cleft involves the frontal process of the maxilla and continues superiorly as a number 12 cleft.

Number 2 Cleft

The Tessier number 2 cleft begins in the region of the Cupid's bow and continues superiorly through the middle third of the nostril rim (Fig. 26-22). Unlike the notched dome of the number 1 cleft, the alar involvement has a hypoplastic appearance, resulting in more of a flattened appearance of the lateral aspect of the nose. Superiorly, the cleft courses as a soft tissue groove to an asymmetrically broadened nasal root with displacement of the inner canthus. The lacrimal system, palpebral fissure, and eyebrows remain uninvolved.

In the alveolus the fault begins in the lateral incisor region to involve the lateral portion of the base of the piriform aperture. Unlike the number 3 cleft, the lateral nasal wall is spared, and the maxillary sinus is not in continuity. Superiorly, the cleft courses obliquely through the junction of the nasal-frontal process of the maxilla without involving the orbital rim. The medial canthus and palpebral fissure are uninvolved. As the cleft comes through the lateral ethmoidal labyrinth, hypertelorism results. Its cranial extension is the number 12 cleft.^{9,10,92,102,104}

Number 3 Cleft

Similar to the number 2 facial cleft, the Tessier number 3 cleft begins as a common cleft of the lip. However, as it continues cephalad, the cleft passes through the nasal alar-cheek junction and continues along the lateral nasal margin to involve the medial aspect of the lower eyelid, just medial to the inferior nasolacrimal punctum (Fig. 26-23). As such, the lower canalicular system is malformed and beyond repair, and the nasolacrimal drainage is disrupted and prone to recurrent episodes of infection. Unlike the number 2 cleft, the medial canthus is involved; it is displaced inferiorly and the canthal ligament is hypoplastic. As a result of the cleft, there is significant soft tissue deficiency in the vertical dimension between the alar base and lower eyelid. The ocular globe may be normal but dystopic or microphthalmic. As the cleft courses superiorly, the medial third of the upper eyelid and brow may be involved as a number 11 cleft.

Fig. 26-23 The number 3 cleft. The cleft undermines the alar base and continues superiorly, medial to the inferior punctum, and interrupts the nasolacrimal system to involve the medial canthal structures. The cleft disrupts the lateral nasal wall and orbital floor. As a result, the orbital, maxillary, and nasal cavities are in continuity. The cleft continues cranially as a number 11 cleft.

As in the typical alveolar cleft, the skeletal cleft passes between the lateral incisor and canine, but proceeds to disrupt the lateral border of the piriform aperture to involve the medial wall of the maxillary sinus. In contrast to the number 2 cleft, the number 3 cleft continues superiorly to involve the frontal process of the maxilla to the lacrimal groove, involving the medial orbital floor and rim. As such the skeletal disruption can be extensive, with the normally separated cavities of the mouth, nose, maxillary sinus, and orbit in continuity as a result of the cleft. Thus the maxilla is significantly hypoplastic in all three dimensions.*

*References 4, 9, 10, 47, 93, 97, 98, 102, 104, 107, 117-122.

Fig. 26-24 The number 4 cleft. The cleft begins lateral to the Cupid's bow. The ala is undisturbed, although it is often secondarily drawn upward. The cleft continues between the piriform aperture and infraorbital foramen to involve the medial orbital floor. The lateral nasal wall is spared, and only the orbital and maxillary sinus are confluent.

Number 4 Cleft

The number 4 cleft begins midway between the philtral column and the commissure, continues lateral to the nasal ala onto the cheek, and ends in the lower eyelid medial to the inferior punctum (Fig. 26-24). Although the inferior canaliculus is involved, the lacrimal sac and nasolacrimal canal are usually undisturbed. The medial canthal tendon is relatively unaffected, because the path of the fault lies lateral to it. As with the number 3 cleft, there is a severe soft tissue deficiency with the margins of the cleft lip, and the normal ala is drawn into the coloboma of the lower eyelid defect. Similarly, orbital dystopia, which occurs as a result of skeletal involvement and microphthalmia, has been described. Superiorly, the cleft continues as a number 10 cleft to involve the middle third of the upper eyelid and eyebrow.

The bony discontinuity cleft begins between the lateral incisor and canine, courses lateral to the piriform aperture through the anterior maxillary wall, and medial to the inferior orbital

Fig. 26-25 The number 5 cleft. In contrast to the number 4 cleft, the number 5 cleft begins near the oral commissure and courses toward the lateral orbital region. On the facial skeleton, the cleft lies lateral to the infraorbital foramen.

foramen, to end at the medial orbital rim and floor. Unlike the number 3 cleft, the piriform aperture and normal bony septation between the maxillary sinus and nasal cavity are spared, and in its complete form, only the oral cavity, maxillary sinus, and orbit are in continuity.*

Number 5 Cleft

The number 5 cleft begins just medial to the oral commissure and follows a more oblique path than the number 4 cleft onto the lateral aspect of the cheek to terminate within the region of the middle and lateral thirds of the lower eyelid (Fig. 26-25). As a result, the vertical soft tissue deficiency of the midface occurs more laterally between the lateral lip element and lower eyelid cleft. Vertical orbital dystopia and microphthalmia are thought to occur. Superiorly, the cleft continues as the number 9 cleft to involve the lateral third of the upper eyelid and brow. Its osseous path begins in the alveolus distal to the canine in the premolar region and continues superiorly across the anterior maxillary wall lateral to the inferior orbital foramen to enter the orbital rim and floor. As with the number 4 cleft, the oral cavity, maxillary sinus, and orbit may be in continuity.†

Number 6 Cleft

The soft tissue cleft begins at the junction of the middle and lateral third of the lower eyelid and continues inferiorly toward the angle of the mandible, as a crease, to give the appearance of an antimongoloid slant (Fig. 26-26). The external ear is not typically involved, although a hearing deficit is frequently described. Its osseous component is characterized by a hypoplastic zygoma, with the cleft running through the zygomaticomaxillary suture. At the level of the orbital rim and floor, the cleft opens into the inferior orbital fissure. Although a true cleft of the alveolus has not been described, the posterolateral aspect of the maxilla is hypoplastic in the molar region.‡

Fig. 26-26 The number 6 cleft. The cleft is recognized as an incomplete form of Treacher Collins syndrome with a coloboma of the lateral lower eyelid and malar hypoplasia. The zygoma is present but hypoplastic, with the cleft in the region of the zygomaticomaxillary suture.

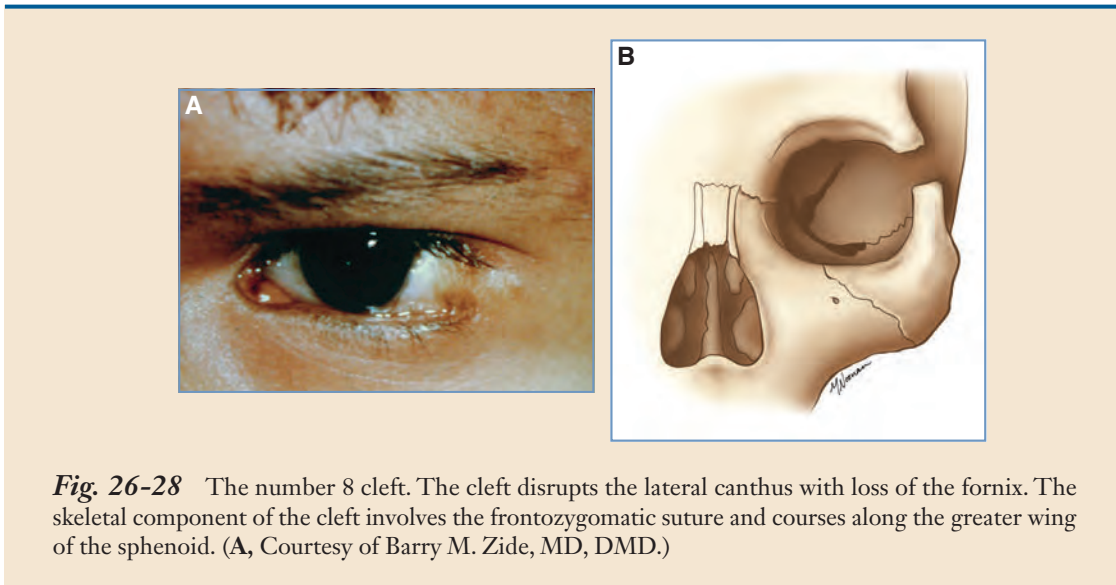

Fig. 26-27 The number 7 cleft. More commonly known as *craniofacial microsomia*, the cleft has a broad spectrum of presentation, with varying degrees of soft tissue and skeletal involvement. The soft tissue component ranges from macrostomia to varying degrees of microtia. The skeletal component of the cleft involves the mandible and zygomatic arch to varying degrees. The maxilla, zygomatic body, orbit, and cranium may be involved. The skeletal component of the number 7 cleft has been further subdivided by classification schemes described by Pruzansky, Munro and Lauritzen, and Vento et al.

Number 7 Cleft

The fault line of the number 7 cleft extends along the transverse crease between the oral commissure and auricular tragus¹³¹⁻¹³³ (Fig. 26-27). The soft tissue deficiency varies from an isolated occurrence of macrostomia or preauricular tags alone, to more severe soft tissue involvement of all intervening structures. The ipsilateral tongue and soft palate may be involved. The parotid gland and duct may be hypoplastic or absent. Occasionally, fifth and seventh cranial nerve palsies can occur. The muscles of mastication—the temporalis, masseter, and pterygoid—may be under-

developed and confluent. The auricular deformities involve not only the external auricle but also the auditory canal and middle ear ossicles.

The skeletal cleft courses between the zygomatic and temporal bones. The zygomatic arch is disrupted, and along with it, the mandibular coronoid process, condyle, and ramus are hypoplastic to varying degrees. The condyle may be distorted or absent altogether. The ramus may be short with a loss of the gonial angle. With the vertical shortening of the mandibular ramal height and posterolaterally the maxilla, the occlusal plane is canted cephalad on the affected side. In the maxillary molar region, the fissure continues between the maxillary tuberosity and pterygoid plate.^{9,10,98,102,104}

Tessier's cleft number 7 is more commonly recognized in the literature as hemifacial microsomia, mandibulofacial dysostosis, and first and second branchial arch syndrome.^{13,129} Goldenhar syndrome is closely associated and has the additional features of epibulbar dermoids and vertebral anomalies.¹³⁰ When bilateral, the number 7 cleft is also found in Treacher Collins syndrome or mandibulofacial dysostosis. The various classification schemes by Pruzansky,¹³¹ Munro and Lauritzen,¹³² Vento et al,¹³³ and others for hemifacial microsomia can be included within the context of the number 7 cleft to further order the degree of involvement.

Number 8 Cleft

The number 8 cleft begins at the lateral canthus and continues posteriorly into the temporal region. The soft tissue defect can be merely a depression at the level of the lateral canthus or a true cleft of the lateral commissure. The defect is characterized by a strip of intervening skin between the upper and lower eyelids, obliterating the depth of the conjunctival fornix (Fig. 26-28). The cleft prevents continuity of the orbicularis oculi muscle and fixation of the lateral canthal tendon. Its osseous component begins in the region of the frontozygomatic suture and can involve the greater wing of the sphenoid.^{9,10,100,104,106}

Facial Clefts 6, 7, and 8 Combination

Tessier^{9,10,98,102} recognized the bilateral combination of clefts 6, 7, and 8 as characterizing the physical findings of patients previously described in the literature with Treacher Collins syndrome or mandibulofacial dysostosis (Fig. 26-29). The course of clefts 6, 7, and 8 isolates the zygoma, and its absence is the hallmark of the complete form of the syndrome. Cleft 6 accounts

Fig. 26-29 Numbers 6, 7, and 8 cleft combination. The cleft results in an absence of the zygoma, with the greater wing of the sphenoid forming the lateral orbital rim. In the bilateral form, the skeletal deformity is characteristic of the Treacher Collins syndrome malformation: malar hypoplasia, downward slanting (antimongoloid) palpebral fissures and lower eyelid colobomas.

Fig. 26-30 The number 9 cleft. The cleft begins in the superolateral portion of the orbital roof through the greater wing of the sphenoid and courses more obliquely to involve the frontal, temporal, and parietal bones.

for the eyelid coloboma and bony hypoplasia at the zygomaticomaxillary suture. The number 7 cleft contributes to the auricular malformation and macrostomia defects, fusion of the temporalis and masseter muscles, and the osseous zygomaticotemporal and mandibular deformities. Cleft 8 completes the syndrome with the zygomaticofrontal (lateral orbital wall) deformity and antimongoloid slant with loss of lateral canthal fixation. Incomplete forms of the syndrome can then be described by various combinations of the number 6, 7, and 8 clefts.^{9,10,98,102}

Number 9 Cleft

Beginning with the number 9 cleft, the clefts become northbound and involve the superior orbital and frontal cranial region. The osseous fault of the number 9 cleft begins in the superolateral portion of the orbital roof through the greater wing of the sphenoid and courses more obliquely to involve the frontal, temporal, and parietal bones (Fig. 26-30). Likewise, the path of the soft

Fig. 26-31 The number 10 cleft. The cleft courses through the central upper eyelid, with colobomas of the eyelash and brow. The central orbital roof and frontal bone are disrupted, and the cranial defect is often occupied by a frontoorbital encephalocele, resulting in an inferolateral orbital dystopia. Its southbound extension is described by the number 4 cleft.

tissue defect courses through the lateral third of the upper eyelid, as does the eyebrow, and into the temporal hairline. The cleft is regarded as the cranial extension of the number 5 cleft.*

Number 10 Cleft

The number 10 cleft involves the middle third of the supraorbital rim, involving the frontal bone and orbital roof lateral to the supraorbital foramen (Fig. 26-31). An encephalocele is often associated with the orbital cleft, resulting in secondary orbital dystopia.

Likewise, soft tissue involvement results in a coloboma of the middle third of the upper eyelid and brow. The extent of lid involvement is variable. Ablepharia has been described, as well as an attempted duplication of the medial third of the lid margin presenting as a transverse split. Ocular anomalies, including colobomas of the iris, may also be associated with this cleft. The frontotemporal hairline may be disrupted in the course of the cleft.^{9,10,98,102,104}

Number 11 Cleft

The number 11 cleft is the cranial extension of the number 3 cleft. As the bony discontinuity continues cephalad, the osseous path can either take a more medial route through the ethmoidal labyrinth or a course lateral to the ethmoid bone to disrupt the medial third of the orbital rim (Fig. 26-32). The medial course results in a unilateral hypertelorism, and the more lateral course results in a coloboma of the medial third of the upper eyelid and proceeds to involve the corresponding medial third of the eyebrow and the frontal hairline.^{9,10,98,102,104}

Number 12 Cleft

As the number 2 cleft courses superiorly to involve the cranium, it continues as a Tessier number 12 cleft. The cleft passes between the junction of the nasal-frontal process of the maxilla and nasal bone to involve the ethmoidal labyrinth, resulting in hypertelorism (Fig. 26-33).

*References 9, 10, 92, 94, 98, 102, 104-107.

Fig. 26-32 The number 11 cleft. The cleft disrupts the medial third of the upper eyelid and brow. Its osseous path results in either clefting of the medial supraorbital rim or hypertelorism, with involvement of the ethmoidal labyrinth. Its southbound extension is described by the number 3 cleft.

Fig. 26-33 Intracranial view of hypertelorism. **A**, Widening of the ethmoidal labyrinth is seen with the number 12 cleft. **B**, Widening of the olfactory groove and cribriform plate occurs with the number 13 cleft. **C**, The width of the crista galli is greater in the number 14 cleft. (Courtesy of Paul Tessier, MD.)

Fig. 26-34 The number 13 cleft. The cleft courses superiorly medial to the eyebrow as the cranial extension of the number 1 cleft. Hypertelorism is a common feature, with widening of the olfactory groove and cribriform plate.

Unlike the Tessier number 13 cleft, the skeletal fault is lateral to the olfactory groove, and the cribriform plate is of normal width. Although the medial canthus and upper lid are uninvolved, the cleft may disrupt the medialmost portion of the eyebrow.^{9,10,96,102,104}

Number 13 Cleft

The number 13 cleft is the northbound or cranial extension of the paramedian number 1 cleft. The fault lies medial to the junction of the nasal bone and frontal process of the maxilla, to involve the ethmoidal labyrinth and olfactory groove, resulting in widening of the cribriform plate and hypertelorism (Fig. 26-34; see Fig. 26-33). The characteristic finding is a widening of the olfactory groove.

The medial portion of the eyebrow can be dystopic without an obvious crease, and often there is an omega-shaped distortion of the hairline as the underlying skeletal cleft enters the cranium.^{9,10,98,102,104}

Number 14 Cleft

The number 14 cleft returns to the midline of the cranium. As with its facial counterpart, the number 0 cleft, it is part of the median craniofacial dysraphia and includes the median cleft face syndrome (hyperplasia) and holoprosencephaly (hypoplasia) (Fig. 26-35; see Fig. 26-33).

The latter situation is characterized by hypotelorism and the previously discussed features of holoprosencephaly. The central midline cranial base structures may be hypoplastic to varying degrees, and the orbits allowed to converge to the midline. The cranium is microcephalic, and the forebrain abnormality is proportional to the degree of facial disorganization.

Hypertelorism, which is at the other end of the spectrum and more commonly seen, has an increased width in the interorbital distance. The cranium may be bifid. The crista galli may be

Fig. 26-35 The number 14 cleft. **A** and **B**, The number 14 cleft is the cranial extension of the number 0 cleft, and as such, may present with tissue excess (hypertelorism). **C** and **D**, Alternatively, it may present with tissue deficiency (hypotelorism).

widened, duplicated, or absent. The distance between the olfactory grooves is increased, but the olfactory groove itself is uninvolved and of normal width. Unlike the number 13 cleft, the cribriform plate is of normal width. The bony defect may give rise to a frontal, frontonasal, or frontoethmoidal encephalocele. As a result, the cribriform plate may be inferiorly displaced as much as 20 mm below the level of the orbital roof, when it is normally only 5 to 10 mm. The frontal bone may be flattened or with a central defect when an encephalocele is present. The radix is broad, and the nasal bone is splayed out as the defect courses southbound in continuum with the number 0 cleft.*

Table 26-7 Tessier 0-14 Classification of Median Craniofacial Dysplasia

Tessier 0-14 Axis	Description
I. Median Craniofacial Hypoplasia	Tissue deficiency
A. Holoprocerephaly spectrum (alobar brain)	Single holistic brain with midline facial hypoplasia or agenesis
1. Cyclopia	Single eye in a single orbit, arhinia with proboscis, often located above the single orbit and microcephaly
2. Ethmocephaly	Severe hypotelorism but separate orbits, arhinia with proboscis located between the orbits
3. Cebocephaly	Severe hypotelorism, proboscis-like rudimentary nose
4. Primary palatal agenesis	Hypoplastic or agenesis of the premaxilla
B. Median cerebrofacial hypoplasia (lobar brain)	Separate lobes to the brain but with midline cerebral malformation; midline facial hypoplasia
C. Median facial hypoplasia	Midline facial hypoplasia without gross cerebral involvement
D. Microforms of median facial hypoplasia	Binder anomaly Central single maxillary incisor Absent upper lip frenulum
II. Median Craniofacial Dysraphia	Normal tissue volume
A. True median cleft	Isolated cleft of the upper lip or abnormal split between the median globular process; can be an incomplete or complete form
B. Anterior encephalocele	Cystic malformation in which the CNS is abnormally displaced or herniated through a defect in the cranium
III. Median Craniofacial Hyperplasia	Tissue excess Tissue excess or duplication All forms of excess tissue starting from thickened or duplicated septum to severe forms of frontonasal dysplasia

Numbers 0-14 Craniofacial Cleft Axis

The median craniofacial dysplasias reviewed in the previous section have been subclassified previously by DeMyer et al⁸⁰ in Tables 26-2 and 26-3. The recent reclassification (Table 26-7) by Kawamoto⁹ may provide a more orderly organization of this grouping of patients along the Tessier 0-14 axis from tissue deficiency to tissue excess.¹³⁴

Number 30 Cleft

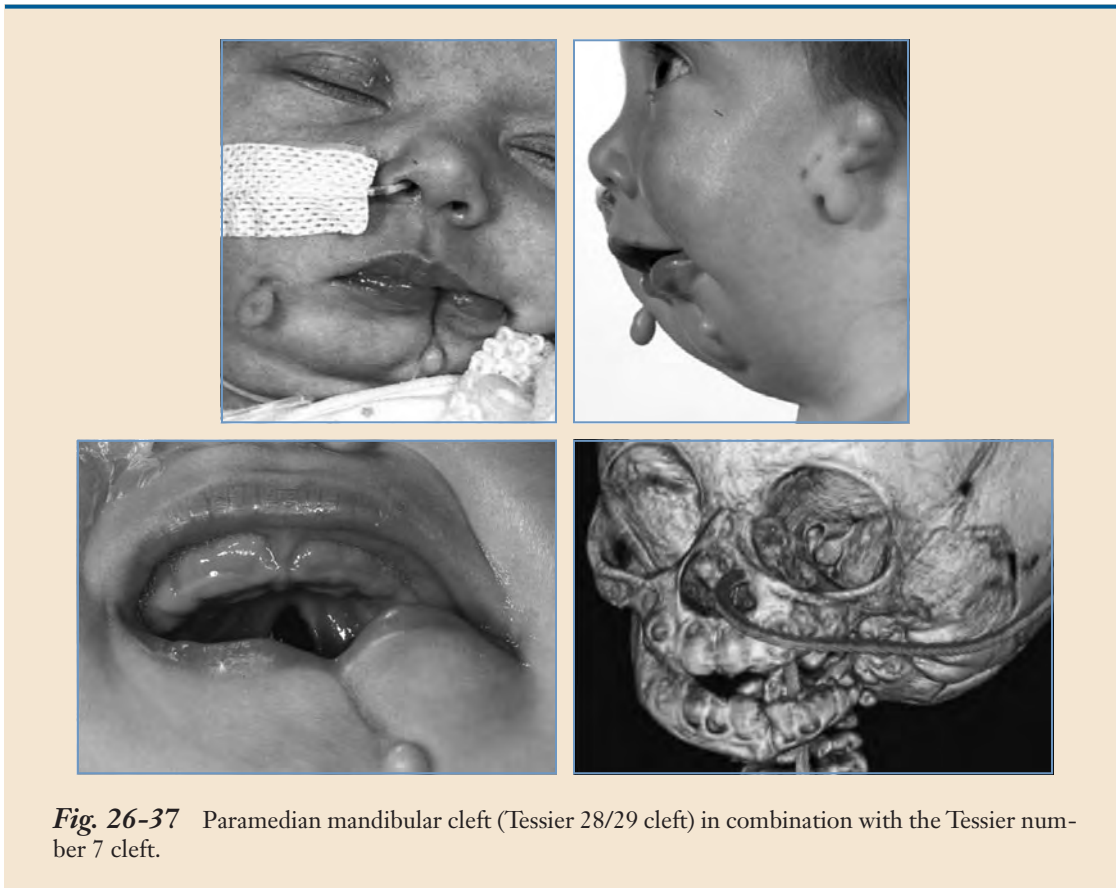

Tessier tentatively labeled the median cleft of the mandibular process as the number 30 cleft to leave the classification scheme open to also include additional paramedian clefts. It is the caudal extension of the number 0-14 cleft. The central defect in the lower lip may range from a minor

Fig. 26-36 The number 30 cleft. Varying degrees of involvement of the median mandibular symphyseal cleft have been reported in the literature, ranging from the commonly seen cleft chin to involvement of the lower lip, alveolus, tongue, and cervical regions.

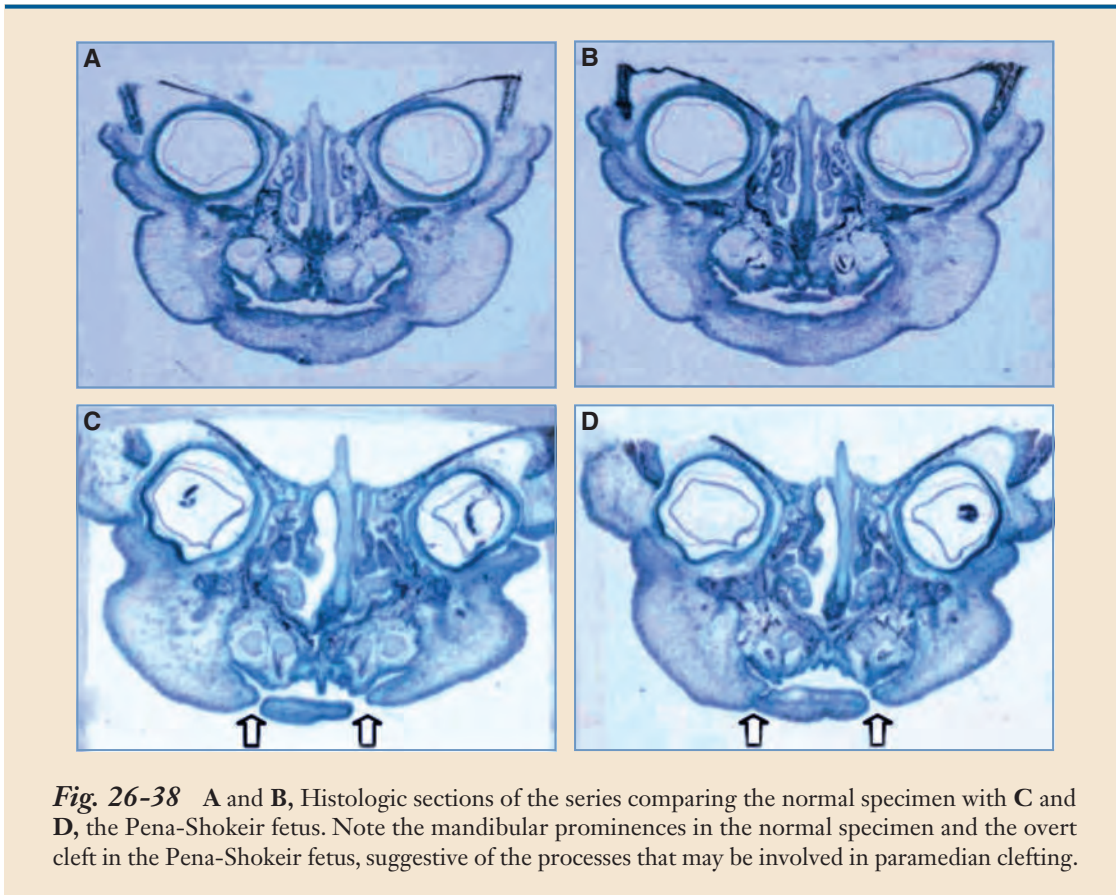

notch in the vermillion to a true median cleft with involvement of the entire vertical length of the soft tissue¹⁴² (Fig. 26-36). Varying degrees of involvement of the tongue have been reported. The tongue may be absent or more commonly bifid. The medial margins of the bifid tongue may be bound down to the margins of the cleft. The complete duplication of the tongue is at the extreme. The cleft in the mandibular alveolus begins between the central incisors and extends to involve the mandibular symphysis.¹³⁵⁻¹⁴²

As the median cleft continues caudally to involve the lower branchial arches, the structures derived from them are involved. The hyoid bone, thyroid cartilage, and sternum may be clefted, and the associated musculature may be hypoplastic. A congenital neck cord may be present as a pathognomic sign of the underlying cleft.¹⁴³⁻¹⁴⁷

Tessier 28/29 Cleft: Paramedian Mandibular Cleft

Tessier did not formally designate a number for the paramedian mandibular clefts, probably because of its rarity. He may have also decided to leave the classification scheme open until there were sufficient clinical cases available for an orderly scheme. Only a handful of cases have been documented in the literature within the past century. Among the earliest is the case in 1952 of a newborn with ankyloglossia and symmetrical bilateral clefts of the lower lip.¹⁴⁸ However, the three additional cases in the literature have been a unilateral paramedian mandibular cleft and associated with varying degrees of hemifacial microsomia and Goldenhar syndrome.¹⁴⁹⁻¹⁵² Within the existing Tessier nomenclature, these rare paramedian clefts would be numbered between Tessier 14 and 30 clefts. Morrisset et al¹⁵¹ suggest a paramedian cleft of the lower lip in the case they present as a Tessier 28/29 (Fig. 26-37).

Although the median mandibular cleft can be simplistically understood as failure of fusion of the paired first branchial arches, the existence of paramedian clefts then belies an explanation. There must be another process at the embryologic level that accounts for both the median and paramedian clefts. In their detailed study of the Pena-Shokeir fetus, Vastardis et al¹⁵³ found a set of paired paramedian surface furrows that separated the central mandibular region from the lateral elements (10 to 16 mm CR length, day 38). Thus failure of growth center differentiation could account for the contribution to the bilateral and unilateral forms of mandibular paramedian clefts. Therefore the median cleft could be considered a bilateral form without the central portion of the symphysis (Fig. 26-38).

MANAGEMENT OF FACIAL CLEFTS

General Principles

Given the rarity and unique nature of the clinical expression of each of the craniofacial clefts, the treatment plans cannot be standardized but must be based on the individual assessment of each case (Figs. 26-39 through 26-41). Nevertheless, there are general principles by which the sequence and timing of staged osseous and soft tissue reconstruction can proceed.

Fig. 26-39 In more complex clefts, reconstruction requires staging the soft tissue and skeletal components based on potential treatment of vital structures and growth development of the child. In infants reconstruction involves repairing the upper eyelid defect with a tarsal advancement flap, initial nasal reconstruction with inferior advancement of the nasal dorsal tissue, and macrostomia repair. The correction of the bifid nose and hypertelorism is delayed until later in childhood.

Fig. 26-40 Atypical cleft lip reconstruction. Overlaying cephalometric tracing paper is useful for planning. Right lower lid coloboma reconstruction is planned.

Fig. 26-41 Complex atypical craniofacial cleft reconstruction that required tissue expansion.

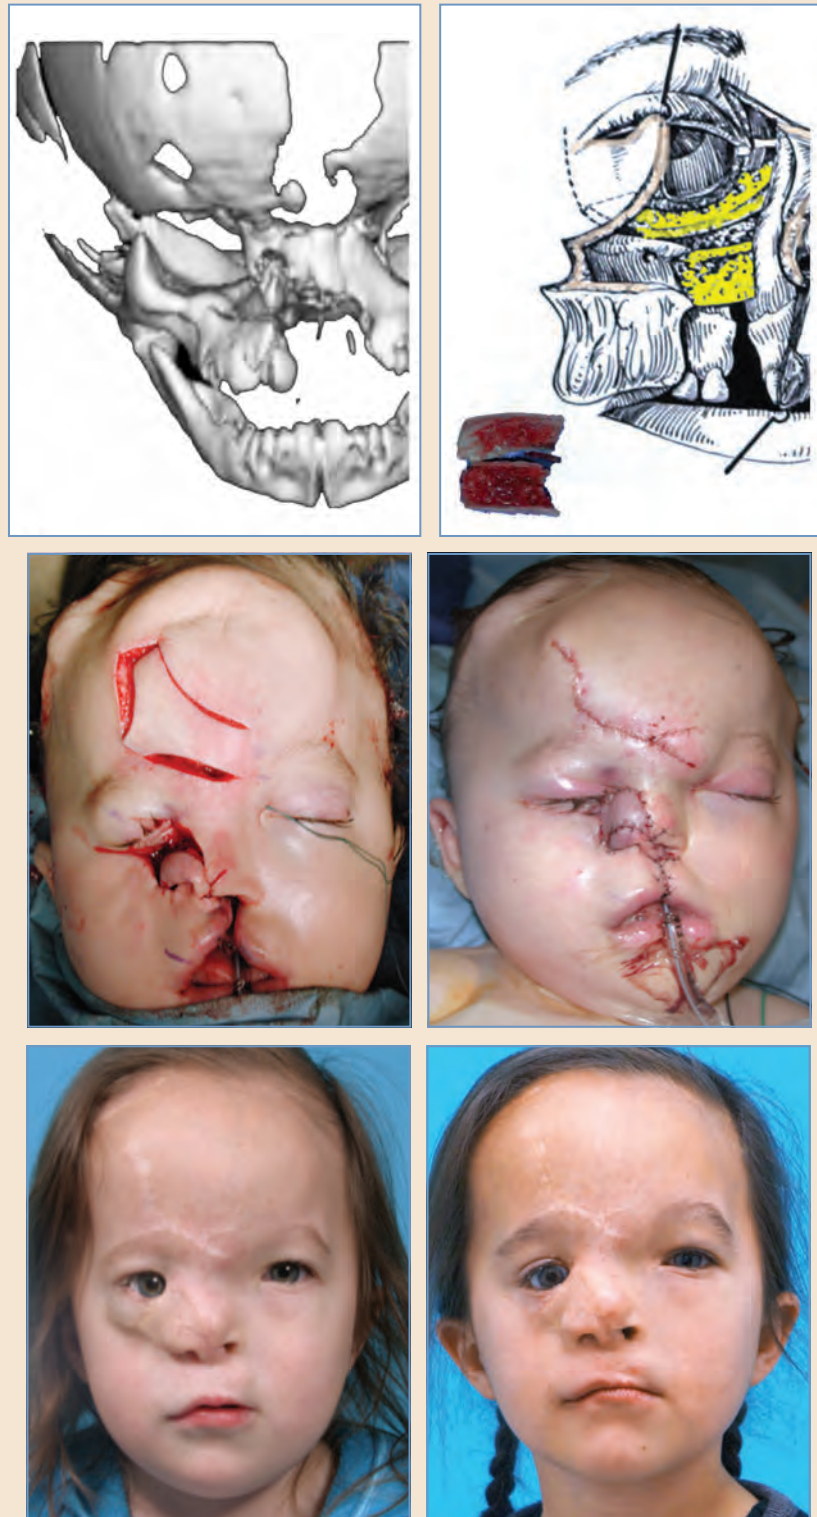

Fig. 26-41, cont'd At initial surgery, the skeletal defect was reconstructed with rib grafts to provide support for the soft tissue flaps. The cleft palate was reconstructed simultaneously. Further reconstruction is planned.

The defect can be corrected with a single operative procedure only in the mildest expression of the facial cleft. As such, most of the cases that the surgeon encounters will require careful staging of the reconstruction. The two questions that the surgeon must answer include (1) what should be the sequence of skeletal and soft tissue reconstruction based on the relative inventory of the involved anatomic structures, and (2) what are the consequences of each of the staged procedures and the durability of the reconstruction with continued growth of the child?

The severity of the malformation in terms of a potential threat to a vital structure, such as the eye, dictates an early intervention. The initial reconstruction should begin as soon as the infant is physiologically able to withstand anesthesia and the surgical insult. When the actual cleft deformity does not pose a significant risk, an appropriate delay can take advantage of the growth of the child, with an appreciable increase in the size of the component structures that facilitate accurate alignment and appropriate positioning of the key landmarks.^{10,154,155}

The initial operative intervention is generally limited to the soft tissue structures. Even a minimal crease as an expression of a facial cleft may involve all underlying layers, including subcutaneous tissue and muscle. The intervening abnormal tissue within the region of the cleft must be excised to expose the normal structures and then accurately aligned to reconstruct the anatomy. Failure to meticulously restore the continuity across the cleft can result in a loss of muscular animation or may leave a persistent stigmata, such as a depressed scar, because of the lack of appropriate soft tissue support. When the repair crosses the lines of minimal tension, the closure should be redirected to a more favorable position with multiple Z-plasties. When there is a difference in the length of the vertical height between the two sides of the cleft, carefully planned rotation/transposition flaps, along with multiple Z-plasties, can be used to restore the length and proper position of the anatomic landmarks on the face. In designing the regional flaps, it is important to remember the soft tissue facial units, and that the scars are best camouflaged by the natural folds and creases to avoid a patchwork quilt appearance to the soft tissue repair.^{8,10,120,155,156}

When the regional tissue is considered insufficient to correct with local flaps alone, an alternative approach is to use tissue expanders to restore the soft tissue defect with adjacent expanded skin of similar color, texture, and appearance. Expanding the soft tissue envelope before skeletal restoration may be beneficial. The success of a bone graft depends on adequate soft tissue vascularity and an envelope free of tension. Furthermore, in later stages, expansion of the regional tissue may allow excision of grossly scarred regions from multiple previous operations and resurfacing with soft tissue of improved color, texture, and vascularity.¹⁵⁷

Although repair of the soft tissue deformity can splint the bony discontinuity and potentially mold the underlying distorted facial skeleton without proper restoration of the structural skeletal support to the soft tissue reconstruction, the stigmata of a facial cleft will always remain. Moreover, a maxillary alveolar cleft creates structural instability of the midface and segmental collapse. The time to optimally intervene remains unsettled. Early manipulation of the underlying bony skeleton in the region may potentially disturb normal midface development. Bone grafting the cleft defect early may lock the maxillary segments in place and interfere with the normal direction of growth and remodeling. Although arguably the inherent growth potential in these patients remains unknown and may possibly be limited because of the severity of the anomaly, early restoration of the skeletal contour can significantly lessen the deformity and allow the child to be “mainstreamed” earlier into society. However, what may be an acceptable result at age 5 or 6 years may be less than ideal in the long-term.^{10,126,158,159}

Although the cranial vault grows rapidly in the first year of life, it levels off earlier than the rest of facial development. The upper midface grows at a slower rate in infancy, but it continues to grow later in childhood and early adolescence. In contrast, growth of the lower midface and mandible, which is determined by eruption of the dentition, continues well into adolescence. The overall growth of the cranioorbitozygomatic regions reaches approximately 85% of its adult size by 5 years of age.¹⁶⁰ Consequently, skeletal reconstructive surgery involving the upper midface

(cranioorbitozygomatic region) should be relatively stable after 5 to 6 years of age. In contrast, reconstruction of the maxillary-mandibular complex should be delayed until adolescence, although there are exceptions. Unless significant functional concerns arise, the timing of reconstruction should be based on an understanding of the normative residual growth expected within the operated region of the facial skeleton.¹⁰

Fundamental principles of plastic surgery procedures apply to all facial clefts. However, specific considerations arise as the individual clefts are addressed.

Number 0-14 Clefts

The true median cleft of the upper lip is repaired by excision of its margins, approximating the muscle layer and accurately aligning the vermilion border to restore the philtral width. The frenulum should be excised when it can result in a diastema of the central incisors. Correction of the bifid nose requires excision of the central furrow and medial displacement of the alar cartilage and nasal bone osteotomies. A dorsal bone graft (cranial or rib) may be required for structural support and increasing the anterior projection of the nasal tip.^{10,110,161}

When there is an associated hypertelorism, a facial bipartition should be considered to simultaneously correct the interorbital width, nasal deformity, and centrally collapsed dental alveolar arch. Depending on the extent of the interorbital involvement and level of the cribriform plate, either an intracranial or subcranial approach is used. Osteotomies are made to mobilize the hemiface. Laterally, the zygomatic arch is cut, and the osteotomies of the lateral orbital wall are extended to the pterygomaxillary junction. Medially, the osteotomy of the palate and premaxilla is completed, and the central mass of the widened nasal skeleton and ethmoid is resected to correct the interorbital width. As the two halves of the face are mobilized medially, the central part of the face is elongated. The palpebral angulation is improved with rotation of the orbit, and the anterior open bite is corrected with the dental arch leveled and the transverse palatal width increased.*

At the other end of the spectrum of the 0-14 clefts are the cases of holoprosencephaly-related malformations, characterized by central hypoplasia. Infants with cyclopia, ethmocephaly, or cebocephaly (groups I through III of the DeMyer et al⁸⁰ and Elias et al⁹⁰ classifications) do not survive infancy and surgical intervention would be inappropriate. In contrast, surgical reconstruction should be offered to infants with less severe neurologic compromise. Infants who fall into group IV (lobar brain morphology) are likely to survive, and repair of the false median cleft lip and palate could be offered. Because these children are invariably mentally retarded, more extensive procedures would be of little benefit. In contrast, within the group of children with grossly normal brain anatomy (group V), a subcranial LeFort III with facial bipartition can be offered to correct the hypotelorism, midface retrusion, and transverse maxillary arch deficiency.^{90,115}

Clefts 1 and 2

Similar to the familiar cleft lip and palatal deformity, the cleft in the Cupid's bow region can be repaired by well-described rotation-advancement techniques. The correction of the alar deformity of the first and second cleft may require either cartilage or composite grafts to the alar rim. More significant disruptions require a complex design of internasal lining and overlying cutaneous flaps with cartilaginous support. The dentoalveolar segment will require bone grafting at the time of mixed dentition coordinated with orthodontic treatment.†

*References 10, 18, 111, 154, 155, 162.

†References 8, 10, 155, 156, 163, 164.

Clefts 3, 4, and 5

Cleft 3

Although the cleft of the lip begins in the Cupid's bow region, it disrupts the alar base and medial canthal region. As a result of the discontinuity, the vertical dimension of the soft tissue between the medial canthus and ala is foreshortened, with the ala rotated cephalad and the medial canthus drawn caudally. Restoring the symmetry of the elements and proper vertical dimension may require the use of an asymmetrical Z-plasty or rotation/transposition flaps with extensive undermining of the soft tissue of the cheek. The medial canthal ligament is hypoplastic, and repositioning the canthus superiorly medial to an anatomic position requires the use of transnasal wiring (Fig. 26-42). As a result of the path that the cleft takes, the nasolacrimal system is disrupted and prone

Fig. 26-42 The number 3 cleft repair. **A-D**, Transposition Z-plasty flaps are used to reposition the medial canthus superiorly and medially while simultaneously lowering the raised ala. Elevation of the transposition flaps, transnasal medial canthopexy, and closure after bone grafting of the underlying skeletal defect are shown. **E**, A single transposition flap may be insufficient to correct the cleft ala. Each cleft is unique and tests the ingenuity of the surgeon to design various local regional flaps to reconstruct the tissue deficiency.

to repeated infections. Often beyond repair, the most satisfactory result is obtained by complete removal of the sac, duct, and canalicular system during the initial soft tissue reconstruction.

In the complete form, the normal nasal maxillary septation is absent, and the oral, nasal, maxillary sinus, and orbital contents are in continuity. The orbital volume and contour of the inferomedial orbital rim is restored with bone grafts, with mucosal lining obtained from adjacent nasal and maxillary mucosa. Bone grafting of the dentoalveolar segment and anterior maxillary wall to support the perialar region should await the stage of mixed dentition.*

Cleft 4

With the cleft of the lip occurring lateral to the philtrum, the lip repair requires discarding the entire labial tissue between the philtral column to the cleft edge. Failure to excise the tissue seems to result in a less than optimal result with the orientation of the scar, persistent appearance of macrostomia, and deficiency of the orbicularis oris muscle in the cleft region (Fig. 26-43).

*References 8, 10, 47, 117, 120, 155, 156, 165, 166.

Fig. 26-43 The number 4 cleft repair. Triangular and quadrilateral transposition flaps are used to restore the vertical dimension and anatomic features. The medial canthus and ala are repositioned. The orbital floor and maxillary defects are bone grafted.

Although the cleft spares the nose and piriform aperture, the ala on the affected side is rotated cephalad, as is the lateral lip element with the deficiency of soft tissue. The decreased vertical height medially is corrected by allowing both the ala and lateral lip element to rotate caudally. This will require wide undermining of the soft tissue and careful design of the interdigitating flaps (see Fig. 26-40).

With the remaining portion of the nasolacrimal system functioning, the disrupted inferior canaliculus is left unreconstructed (see Fig. 26-43). The medial canthal tendon is intact and can be used to anchor the tarsal plate of the lower lid as it is repositioned medially and superiorly to help protect the globe. The deficiency in the conjunctival fornix may require a mucosal graft. Correction of the orbital dystopia and position of the ocular globe requires bone grafting the defect in the medial orbital rim and floor. The defect in the anterior maxillary wall is grafted to support the overlying soft tissue. Bone grafting of the dentoalveolar segment of the cleft should wait for the stage of mixed dentition, coordinated with orthodontic treatment.*

Cleft 5

Like the number 3 and 4 clefts, soft tissue reconstruction of the number 5 cleft involves rotation/transposition flaps to correct the vertical deficiency. Although the soft tissue approximation is simplified without involvement of the medial canthal region, the obliquity of the scar from the region of the commissure to the lateral portion of the lower eyelid is unfavorable. The interdigitation of the flaps requires respecting the facial units and redirecting the limbs along what will eventually be the natural folds and creases. Repair of the cleft of the upper lip should lie along the nasolabial crease.

Restoration of the skeletal defect is similarly carried out by bone grafting the lateral third of the orbital rim and floor to restore the support to the ocular globe. The dentoalveolar defect in the anterolateral maxillary region will also require bone grafting.^{10,97,155}

Clefts 6, 7, and 8

Cleft 6

The Tessier cleft 6 is usually mild. The soft tissue reconstruction involves correcting the antimonogloid slant of the palpebral fissure and restoring the continuity of the lower eyelid coloboma. The skeletal defect requires bony augmentation of the hypoplastic zygoma to restore the malar height and supporting the globe with bone grafts to the lateral orbital floor and rim. The discontinuity of the lateral zygomaticomaxillary buttress should also be bone grafted.^{10,155,167}

Cleft 7

The number 7 cleft has a broad spectrum of severity, and its reconstruction is tailored to the patient. Treatment planning is complex and various with the age at presentation and degree of soft tissue and skeletal involvement. Most commonly, small preauricular tags may represent the mildest form of the cleft and can be removed early in infancy. Patients with the more severe auricular deformity of microtia can begin reconstruction at 5 or 6 years of age when appropriate. Depending on the degree of auricular dystopia, this may require repositioning the auricular remnant posterior-superiorly and the use of a temporoparietal fascial flap. The auricular reconstruction is described in Chapter 31. The macrostomia seen as a transverse cleft or deep furrow should be repaired early. The margins of the cleft should be excised, the orbicularis muscle identified, and the muscle fibers reoriented to restore the continuity of the circumoral musculature. The technique has been well described in the literature by May,¹⁶⁸ Stark and Saunders,¹⁶⁹ Boo-Chai,¹⁷⁰

*References 10, 18, 47, 97, 126, 155, 164, 165.

Bauer et al,¹⁷¹ and Verheyden.¹⁷² The generalized loss of soft tissue bulk (subcutaneous and muscle) requires the use of either serial dermal fat grafts because of the unpredictability of tissue resorption or a vascularized free tissue (for example, deepithelialized scapular or groin) transfer.^{173,174}

Reconstruction of the skeletal deficiency is dependent on the degree of maxillary and mandibular involvement and the resulting asymmetry and occlusal relationship. Reconstruction may require restoring the continuity of the zygomatic arch, mandibular lengthening (either distraction osteogenesis or conventional rib grafting) at the stage of mixed dentition, and maxillary-mandibular osteotomy when facial growth is complete to correct the end-stage asymmetry.* The treatment planning is described in Chapter 31.

Cleft 8

The soft tissue reconstruction of the number 8 cleft involves reconstructing the normally sharp angle of the lateral canthus by restoring the lateral canthal ligament, depth of the conjunctival fornix, length of the palpebral fissure, and continuity of the oculi muscle. Although direct closure of the lateral canthal defects has been described, the technique of Fuente del Campo¹⁷⁸ is an ideal choice, because it restores the normal form to the region. Flaps are created with the superior and inferior palpebral folds and the intervening tissue in the coloboma. The fibrous tissue of the hypoplastic lateral canthal ligament is then fixed to the orbital rim at the appropriate level. The orbicularis muscle is dissected and approximated. The superior and inferior palpebral flaps are approximated, defining the palpebral width, and the laterally based flap fills the resulting superior and inferior defects.

The bony defect in the lateral wall of the orbit is usually insignificant and is restored when orbicularis oculi muscle is approximated. In rare cases, split calvarial bone may be required in more significant defects.^{10,155,167}

Clefts 6, 7, and 8—Treacher Collins Syndrome

The pseudocoloboma of the lower lid can be improved with either a Z-plasty or an upper-to-lower lid transfer and could be corrected before reconstruction of the orbitozygomatic complex and lateral canthopexy.^{167,179} The auricular reconstruction typically begins at about 6 years of age and is outlined in Chapter 31.

The reconstruction of the Treacher Collins syndrome (bilateral cleft 6, 7, and 8 combination) primarily depends on correcting the underlying skeletal architecture. The deficiency in the lateral orbital wall, anterior floor of the orbit, and inferior orbital rim requires bone grafting to restore the orbital morphology. The antimongoloid slant is corrected by repositioning the lateral canthus and contouring the superolateral orbital slant. Lateral canthoplasty must be performed each time the orbital complex is regrafted, and there is an invariable downward drift despite fixation. The continuity of the zygomatic arch should be reestablished, and additional onlay bone grafts should be done to restore the anterior projection of the hypoplastic malar region. In harvesting the required amount of cranial bone, care must be taken not to injure the vascular supply to the temporoparietal fascia, which may be used to support the skin graft in the auricular reconstruction. The amount of bone required is enormous, and skeletal reconstruction should be delayed until the child is older than 6 years of age. Moreover, as Tessier⁹⁸ has noted, resorption is more severe in Treacher Collins syndrome than in other malformations and requires repeated bone grafts to maintain the bony volume.

To improve the dental relationship and facial balance, maxillary and mandibular procedures are required. Correction of the vertically short posterior maxilla may be achieved by a LeFort I

*References 10, 155, 167, 173, 174-177.

osteotomy or require a LeFort II osteotomy with rotation (not advancement) to lower the maxillary tuberosity and simultaneously enlarge the nasopharyngeal space. To correct class II malocclusion and the anterior open bite deformity, exaggerated even more with the maxillary movement, the mandible is lengthened and advanced. Although a sagittal split osteotomy is possible in some patients, the ramus is often short and narrow, and a V osteotomy with bone grafts is preferred. With this approach, Tessier⁹⁸ describes mandibular advancements of 20 to 25 mm and vertical lengthening of the ramus without practical limits. In addition, osseous advancement genioplasty with elongation of the suprahyoid tissues improves the contour.

When respiratory insufficiency occurs as result of the narrow nasopharyngeal/hypopharyngeal space, surgical intervention may be required. Unlike the adult, the midface in the child must be rotated at the level of a subcranial LeFort III to avoid the developing tooth buds. Recently, the introduction of mandibular osteotomy and distraction osteogenesis may play a role in these cases of children who require a tracheostomy.^{10,167,177,180-182}

Clefts 9, 10, and 11

The soft tissue reconstruction of the number 9, 10, and 11 clefts involves restoring the discontinuity in the upper eyelid and brow with adjacent tissue transfer. The bony cleft in the superior orbital rim and roof requires bone grafting, and the associated deformity in the frontal bone should be augmented to restore the proper projection to the supraorbital region of the brow.

In severe cases of clefts 10 and 11, orbital dystopia and hypertelorism can result and require both an intracranial and extracranial approach.^{10,155,183,184}

Clefts 12, 13, and 14

The reconstructive efforts in the number 12, 13, and 14 clefts are primarily directed to correcting the hypertelorism that results from widening the ethmoidal labyrinth in the number 12 cleft and the cribriform plate, beginning with the number 13 cleft. Both clefts 13 and 14 can present with an encephalocele that must be addressed with both an intracranial and extracranial approach.^{10,155,183} Surgical correction of hypertelorism is discussed in Chapter 25.

Cleft 30

Reconstruction of the mandibular symphyseal cleft involves restoring the continuity of the mandibular skeletal symphysis by approximating and fixation of the mandibular cleft border. Reconstruction of the overlying cleft soft tissue involves restoring the continuity of the orbicularis muscle, midline cervical muscles, and overlying skin with appropriate transposition and Z-plasty flaps. The surgical technique is well described in several publications.¹⁸⁵⁻¹⁸⁷

CONCLUSION

The laws of normal growth are best formulated and understood when the causes of their exception can be established. The experimental method itself rests on the notion that induced and controlled departures from the ordinary can unveil the laws of order. Consequently, congenital malformations are nature's experiment, uncontrolled by intentional human art to be sure, but source of insight nevertheless. The early teratologists sought to understand malformations by classifying them. The early French anatomists developed three categories: missing parts (*monstres par défaut*), extraparts (*monstres par excès*), and normal parts in the wrong places. However, a classification is no more than a set of pigeon holes until the causes of the ordering can be specified.

KEY POINTS

- Atypical facial clefts are 100 times less common than common clefts.
- Radiation, infectious agents, metabolic imbalances, and numerous drugs and chemicals have been implicated as causes of atypical craniofacial clefts.
- Extrinsic mechanical factors, such as from an amniotic band disruption mechanism, have been suggested to explain aberrant locations of clefts not corresponding to any well-described embryologic process.
- Historically, two theories of facial clefting have been described: the classic theory of fusion by Dursy⁵¹ and His⁵² and the theory of mesodermal migration by Veau and Politzer,⁵³ Warbrick,⁵⁴ Stark,⁵⁵ and others. Other more recent theories proposed by Johnston⁵⁶ and Vermeij-Keers et al⁵⁷ have led to possible explanations of some of the rarer defects clinically seen.
- Studies by Vermeij-Keers et al⁵⁷ and others have shown that migration of neural crest cells alone may not account for all varieties of facial clefting. Rather, facial clefts may represent failure of local differentiation of the neuroectoderm and mesenchyme. They identified four primary sites in early embryologic development that could lead to true cleft formation. They are associated with the normal planes of embryologic processes, and their closure occurs sometime within the seventh gestational week.
- After the seventh gestational week, the differentiation of the mesenchyme into facial muscles and supporting bone and cartilaginous support occurs. Ossification centers arise to complete the bone formation. If the ossification centers fail, then pseudoclefts develop. These are not true clefts, and as such, have been termed *secondary clefts or dysplasias*.
- Holoprosencephaly is defined as a spectrum of median facial deformities associated with tissue-deficient median cerebrofacial dysmorphogenesis.
- The various degrees of facial dysmorphism associated with the severity of holoprosencephaly have been grouped into five major types: (I) Cyclopia, (II) ethmocephaly, (III) cebocephaly, (IV) hypotelorism with median cleft lip, and (V) hypotelorism with bilateral cleft lip.
- The degree of correlation between the brain and face is not absolute. The predictive correlation is only about 80%. The scheme of DeMyer et al⁸⁰ has been revised by Elias et al⁹⁰ to reflect those variations of clefting, in which the brain is either near normal or normal despite the facial clefting.

Continued

KEY POINTS (continued)

- DeMyer⁹¹ proposed the term *median cleft face syndrome* to describe this collection of median facial anomalies characterized by near-normal or excess tissue. The dysmorphic features can vary from a subtle midline notch of the upper lip to an obvious bifidity of the nose and in more severe cases hypertelorism. These defects are believed to occur late—after the seventh week of gestation.
- Numerous classification schemes have been proposed for rare atypical clefts. Some are based on the embryology, whereas others are based on the clinical findings. Although a classification scheme, including both a descriptive terminology and insights into the underlying embryology, is preferable, Tessier's system⁹⁸ has proved the most useful clinically.
- In 1976 Tessier's classification system⁹⁸ represented an architectural description of defects rather than true descriptions of the structures involved. The defects are numbered for ease of clinical classification rather than along any pathoembryogenic sequence. Although it fails to provide insight into the underlying etiopathology of these defects, the relative simplicity of this classification has made it almost universally accepted for clinical use.
- The most common cleft types seen are the median clefts 0 and 14, although the transverse cleft, number 7, would be expected to be significantly more common with a stricter definition.
- Careful observation of the atypical cleft anatomy, coupled with a clear understanding of the normal and abnormal embryologic processes that affect each structure, provide both the basis of classification and keys to reconstruction.

This is a classic in cleft lip and palate literature. Five rare embryos with cleft lip and palates (the term "barelip" was still in use) were studied, with serial drawings of volumes of mesoderm present along each side of the cleft. The findings supported the theory of fusion in the secondary palate, but showed a different mechanism, named "mesodermal penetration" occurring in the formation of the lip and remaining primary palate.

This excellent series of articles described in depth the current understanding of facial clefting in the context of modern embryogenesis. It is essential reading for today's pediatric plastic surgeon.
80. DeMyer W, Zeman W, Palmer CA. The face predicts the brain: diagnostic significance of median facial anomalies for holoprosencephaly (arhinencephaly). *Pediatrics* 34:256, 1964.
This and the former paper are both classics on the subject of median facial anomalies. DeMyer et al described the spectrum of holoprosencephaly, with the severe forms showing orbital, nasal, and aural anomalies, all characterized by varied degrees of hypotelorism. The former paper described the group of facial anomalies with midline craniofacial-cerebral dysraphisms, in which true midline clefting is associated with hypertelorism. They also put forth the concept that the facial deformity predicts the underlying brain anomaly, something that we now know is only predictable about 80% of the time.

The authors studied 59 patients treated at their institution over a 14-year period with median facial dysplasias. These cases represented 2% of the clefts seen at their center. They described the findings, which included a poorly defined Cupid's bow, absence of the labial frenulum and anterior nasal spine, deficient columella, and poorly developed septal cartilage and premaxilla. The intelligence tests showed results not significantly different from the noncleft population. They concluded that this group of patients had inherent poor midfacial growth, and that the tissue deficiencies and lack of normal landmarks made reconstruction of the lip and nose difficult.

110. Millard DR, William S. Median lip clefts of upper lip. *Plast Reconstr Surg* 42:4, 1968.
In this paper Millard and Williams presented their experience with the rare median facial clefts. To clarify some of the confusing terminology regarding median facial clefts, they proposed that "any vertical cleft through the center of the upper lip be classified as a median cleft." These were then divided into two groups (1) agenesis of the frontonasal process and (2) a cleft of the median element. Furthermore, if any vestige of the prolabium is present, the cleft should be classified as bilateral.

Orthognathic Surgery in Adolescents With Dentofacial Skeletal Deformities

Pravin K. Patel • Stephen B. Baker

Orthognathic surgery involves the surgical manipulation of the elements of the facial skeleton to restore the normal anatomic and functional relationship in patients with anomalies of the dentofacial skeleton. This chapter will provide an overview of the principles of orthognathic surgery that can be used to manage a broad spectrum of maxillofacial skeletal abnormalities, whether of congenital, developmental, or acquired origin.

The word *orthognathic* comes from the Greek *orthos*, meaning “straight,” and *gnathos*, meaning “jaw”; thus orthognathic surgery means to straighten a jaw. Differentiating a straight jaw from one that is not requires that the surgeon determine the degree of deviation from a specified population norm. Ultimately, restoring the orthognathic form of the face depends on achieving the ideal facial aesthetic for the individual patient and not simply on restoring the average normative values of any given population.

Of course, the face encompasses more than the upper and lower jaws, and when deformities also involve the cranioorbital skeleton, evaluation and management expand the scope of maxillofacial surgery to include craniofacial surgery. Thus orthognathic or maxillofacial surgery should be considered a subcategory of craniofacial surgery.¹

In general, dentofacial skeletal anomalies occur because of a difference in growth between the upper facial skeleton and lower facial skeleton, resulting in a discrepancy in the normal relationship that exists between the upper and lower jaws. The normal growth of the facial skeleton can

be influenced by an underlying genetic predisposition and acquired causes. Congenital anomalies from facial clefts resulting from various syndromic conditions such as Apert and Crouzon syndromes affect normal growth and development. Traumatic events in the mature skeleton can displace the normal elements and require repositioning osteotomies if they are improperly reduced initially, or in the developing facial skeleton, they can interfere with normal subsequent growth. However, the developmental anomalies representing the extremes of population norms are the most common conditions requiring orthognathic surgery.²

Indications for orthognathic surgery include facial dysmorphism with or without functional implications. For example, in patients with retrogenia but without malocclusion, an osseous genioplasty might be considered for facial form. If the retrogenia is associated with retrognathism resulting in malocclusion, then orthognathic surgery is used to restore not only the facial form but also functional occlusion. From a functional standpoint, the goal of orthognathic surgery is to reestablish the following equation:

$$\text{Centric relation} = \text{Centric occlusion} = \text{Habitual occlusion}$$

Thus both function and appearance must be optimized from multiple perspectives.

Maxillofacial deformities can be broadly divided into three major categories: (1) skeletal dysplasias, (2) dental dysplasias, and (3) dentofacial skeletal dysplasias. Dental dysplasias are strictly limited to malocclusions that result from an abnormal spatial relationship of the dentition alone and not because of the skeletal position of the upper and lower jaws. These can be corrected with orthodontic treatment alone. In patients with skeletal dysplasia alone, the dentition is in good alignment, but the maxilla and/or mandible is dysplastic. Skeletal dysplasias require correction of the skeletal deformity without altering the occlusion (for example, in a patient with retrogenia without retrognathia or one with hemifacial microsomia who has a normal maxillary-mandibular dental relationship but an occlusal cant because of skeletal asymmetry). In dentoskeletal dysplasias, the dentition is malpositioned within each arch and between the upper and lower arches; in addition, the skeletal relationship between the upper and lower jaws is abnormal. An example is a patient with a maxillary sagittal and transverse width deficiency resulting from a facial cleft. Correction requires aligning the dentition within each arch with orthodontic treatment and restoring the maxillary-mandibular dental relationship with skeletal osteotomies and repositioning.

Skeletal and dentofacial skeletal dysplasias can be further classified based on the position in space and the volume or mass (whether deficient or excess) of the individual facial elements. For example, the mandible can be of normal shape and volume but retrognathic in relation to the maxilla, or it may be not only retrognathic but also volumetrically deficient. Each of the elements—the zygoma, maxilla, mandible, and chin—can individually be disproportionately affected, leading to a variety of clinical presentations (Fig. 27-1). However, similar clinical appearances can occur as a result of very different structural problems, and determining which facial elements are involved in the deformity requires a systematic evaluation (Fig. 27-2).

EVALUATION OF DENTOFACIAL DEFORMITIES

Correction of maxillofacial deformities requires careful analysis of the soft tissue with clinical examination and supporting photographs, skeletal evaluation with standardized radiographs, and dental evaluation with study models.³⁻⁶ This comprehensive evaluation from multiple perspectives will then generate a list of problems, all of which will need to be addressed to achieve the intended goal.

Fig. 27-1 Diversity of dentofacial skeletal deformities. **A** and **B**, Midfacial deficiency (maxillary retrognathia/hypoplasia) in a patient with a facial cleft. **C** and **D**, Mandibular deficiency (retrognathia/hypoplasia) of developmental origin. **E** and **F**, Vertical maxillary excess with mandibular retrognathia and retrogenia of developmental origin. **G** and **H**, Maxillary-mandibular asymmetrical growth in a patient with hemifacial microsomia.

Fig. 27-2 Range of dentofacial deformities. Class I (*center*) orthognathic deformity. Class II (*left*) dentofacial skeletal deformity. Sagittal maxillary excess and mandibular retrognathia can result in similar appearances. Class III (*right*) dentofacial skeletal deformity. Sagittal maxillary deficiency and mandibular excess can result in similar appearances.

Fig. 27-3 A, Frequently patients will hold their lips together to avoid showing their teeth. This results in mentalis muscle strain. B and C, The lips must be in a relaxed position to clinically assess the lower third facial structures.

Fig. 27-4 Range of variations in the position of the lips and the amount of dental display. A, Lips together; B, relaxed lip position; C, natural smile; and D, broad smile. Ideally, patients should be assessed with the soft tissues (facial muscles) in a relaxed position and the lips in repose. E-H, Patients should be assessed in frontal, lateral, and oblique views with the head in the Frankfort horizontal plane and the eyes parallel with the horizon.

Clinical Assessment

Clinical assessment should be directed specifically at evaluating the degree of zygomatic projection, the maxillary and mandibular positions in space relative to each other and to the cranial vault, and the relative size or proportion of each of the facial elements. However, proper orientation of the head with respect to the horizon is important in determining which elements of the facial skeleton need to be repositioned. Patients with dentofacial deformities may alter their head posture to improve function or make the deformity less noticeable, and it becomes important to adjust for such compensations at the time of clinical, photographic, and radiographic examinations.⁷

Patients should be seated upright and asked to look toward the horizon. The head should be oriented with the clinical Frankfort horizontal plane (the line from the ear tragus to the infraorbital rim) parallel to the floor. Equally, the posture of the lips needs to be standardized.^{8,9} Frequently patients will unconsciously force their lips together to avoid showing too much of their teeth, which results in straining of the mentalis muscle and also affects the chin contour (Fig. 27-3). When patients are being examined, the lips should be in a relaxed position so that there is a natural draping of the soft tissue. With relaxed lip posture, the degree of dental display (lip-to-tooth ratio), evidence of lip incompetence, dental-facial midline discrepancies, and, when combined with relaxation of the mentalis muscle, chin contour can be determined. With the head properly positioned, the head mimics the natural standing posture and helps to standardize the measurements, treatment planning, and assessment of the outcome after orthodontic-surgical treatment.

Examination of the face should be systematic, with assessment of the frontal, profile (lateral), and three-quarter (oblique) views¹⁰⁻¹² (Figs. 27-4 and 27-5). The frontal analysis should focus on recording left-right facial symmetry, the presence or absence of the occlusal cant in the frontal plane, the congruence of the midline structures between the maxillary-mandibular dental midline with the facial midline, the length and posture of the upper lip, and the amount of dental display with the lips in repose and with a natural smile.^{13,14} Examination of the patient in profile

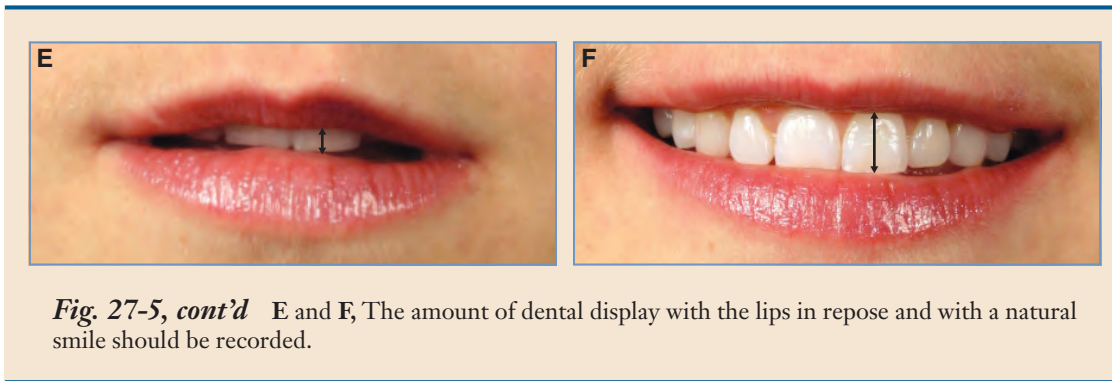

Fig. 27-5 A and B, The cant in the frontal plane and any rotational deformity in the transverse plane should be noted. C, With mouth opening, any deviation (lateral gnathism) should be noted. D, The maximal stomal opening from the maxillary incisal edge to mandibular incisal edge should be recorded.

Continued

will provide the most valuable information for determining the vertical and sagittal relationships of the face. In this view the clinical assessment includes a vertical height analysis, position of the midface relative to the cranial base (sagittal), the position of the mandible relative to the cranial base (sagittal), the position of the mandible relative to the maxilla (sagittal), the position of the chin (symphysis) relative to the mandible, and the position of the chin relative to the upper face, the columellar-lip angle, the depth of the labial mental sulcus, and the cervicomandibular angle. The oblique view adds the third dimension in assessing the degree of zygomatic projection and the perialar region. It is the most useful assessment for determining maxillary-malar deficiency, which may not be fully appreciated in the true lateral view.

The intraoral examination should focus on the overall state of oral hygiene, anatomic and functional tongue abnormalities, the presence or absence of teeth, dental crowding, tooth size discrepancies, the occlusal relationship (Angle classification, open bite, and crossbite; overjet and overbite relationships), the discrepancy between the occlusal relationship and centric occlusion, transverse width discrepancy between the maxillary and mandibular dental arches, and the degree of the curves of Spee and Wilson (Fig. 27-6).

The maxillary-mandibular occlusal relationship should be evaluated with the condyles seated within the glenoid fossa (centric relation) and the teeth lightly touching. When asked to show their bite, patients will frequently not necessarily be in centric relation. Instead, they may bite in their normal habitual occlusal relationship—that is, the occlusion these patients go into when they are unconsciously talking, eating, or swallowing. Many patients find it difficult to relax and allow the examiner to manipulate the mandible into the glenoid fossa (centric relation examination). An alternative is to ask the patient to place the tip of the tongue as far back on the roof of the mouth as possible while gently closing the teeth. Failure to appropriately determine the occlusal relationship in centric relation may lead to an improper diagnosis and a compromised outcome. In patients with dentofacial deformities, the centric relation, centric occlusion, and habitual occlusion are not necessarily equal.^{3,5}

Because temporomandibular joint disorders may coexist with dentofacial deformities, the masticatory function should be documented.^{15,16} The history should focus on headaches, muscle pain, clenching and grinding of teeth, limitations of opening, locking in the open or closed position, and clicking, popping, and pain with functioning of the temporomandibular joint. Patients should be questioned regarding the onset, duration, and factors that improve or worsen these symptoms. The muscles of mastication should be palpated and areas of tenderness noted. The timing of any clicking, grinding, or popping should be noted within the opening and closing cycles. The interincisal opening, protrusion, and lateral excursion should be recorded. The normal maximal stomal opening measures 40 to 56 mm, with lateral excursion in the range of 9 to 13 cm. The pattern of opening and closing with any lateral deviation should also be noted.

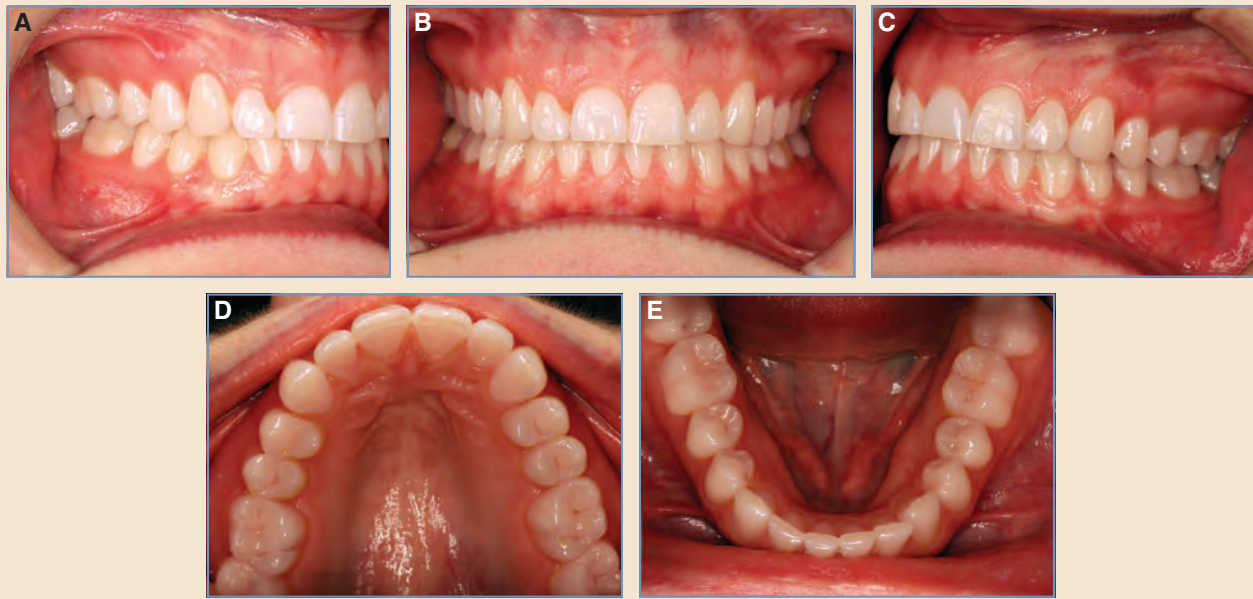

Fig. 27-6 A-C, The dentition in each arch should be assessed (oblique and frontal views). D and E, The occlusal relation between the arches (upper and lower) should be noted.

Based on the results of this clinical examination alone, a decision can be made in most circumstances regarding which jaw needs surgical repositioning to restore the normal anatomic relationship.

Photographic Documentation

Clinical photographs are essential to document the clinical evaluation and to allow photometric analysis.¹⁷ Soft tissue landmarks are used to obtain angular and linear measurements that can help quantitatively define what is “out of place.” Frontal, lateral, oblique, and intraoral photographs should be standardized.⁷ A clear acetate ruler can be placed next to the patient as the photographs are taken for reference measurement; otherwise, a proportionate type of analysis without relying on absolute values can be used. Facial balance is typically assessed by dividing the face into thirds. The upper third goes from the anterior hairline (trichion) to the glabella, the middle third is from the glabella to the subnasale, and the lower third is from the subnasale to the menton. When each of the thirds is equal, the face is said to be balanced and of “ideal” proportions. It is important to remember that facial proportions are only idealized concepts that have changed over time.¹⁸⁻²¹ Such rules merely provide a rule of thumb, and there is a wide range of aesthetically pleasing faces that defy such absolute canons (Figs. 27-7 and 27-8).

In recent years facial images have been captured by a variety of three-dimensional (3D) systems that have begun to transition from the research laboratory to the clinical setting. These provide the ability to “reproduce” the patient’s three-dimensional surface images of the face in a digital media that allows the clinician to manipulate the patient’s head as an object in virtual space and to make objective soft tissue cephalometric measurements. Although the expense of such systems is a significant limiting factor in routinely replacing the traditional two-dimensional (2D+ digital photography, it has the potential to become the standard in the future.

Fig. 27-7 Photometric analysis is used to assess facial symmetry, applying the rule of fifths and the rule of thirds.

Skeletal Evaluation

Skeletal evaluation has traditionally relied on panorex and cephalometric radiographs.²² Panorex radiographs provide an overview of the stage of dental development, the mandibular anatomy, and any gross pathologic findings. Specific films such as occlusal and periapical views can be obtained to further assess the dentition, supporting bone, and interdental spaces. Cephalometric radiographs provide standardized skull/facial views that allow comparison over time to assess growth in individual patients and to compare individual patients against standardized population norms.²³⁻²⁵ Skeletal views can be obtained in lateral and frontal views. Lateral cephalometric radiographs allow an assessment of the elements of the dentofacial skeleton from a sagittal perspective. The maxilla can be related to the mandible, and each can be related to their position in the skull base. A soft tissue profile is simultaneously obtained, which facilitates relating the soft tissue to the facial skeleton. In addition, the upper and lower dentition can be related to each other and each to its own skeletal base, the maxilla, and the mandible.

Basic measurements, based on key anatomic landmarks, are obtained from the cephalometric radiographs and form the basis of cephalometric analysis, providing quantitative assessment (Fig. 27-9).

When cephalometric measurements are analyzed, no single measurement can summarize the dentofacial deformity. The measurements must be analyzed as “collections” or “groupings” to reflect the clinical picture. In addition, the analysis cannot rely on a single reference plane, the SN plane or the FH plane alone, but both must be used to correlate the spatial position of each of the jaws with stable structures. Numerous cephalometric analyses exist; each emphasizes particular skeletal and dental elements. Common analyses include those of Steiner, Ricketts, Delaire, Jarabak, and Sassouni, among others (Fig. 27-10).

Regardless of the analysis used, differences may occur in treatment planning that vary from the findings of the initial clinical assessment. In this instance, the surgeon should rely on the clinical examination. Although these analyses are invaluable, the treatment plan should not focus solely on correcting cephalometric abnormalities. The goal of treatment is not to normalize the patient's cephalometric measurements, but to make the facial appearance aesthetically pleasing while simultaneously establishing a functional occlusion.

Fig. 27-9 The facial skeleton is analyzed using cephalometric radiographs with anatomic landmarks. (*A*, A point; *ANS*, anterior nasal spine; *Ar*, articulare; *B*, B point; *Go*, gonion; *Me*, menton; *N*, nasion; *O*, orbitale; *Pg*, pogonion; *PNS*, posterior nasal spine; *Po*, porion; *S*, Sella.)

Cephalometric analysis, when used appropriately within its limitations, can provide the objective evidence needed to guide but not determine treatment planning and assess treatment outcomes (Table 27-1).^{26,27} For the surgeon, the analysis must be clinically workable, simple to use, and directly correlated with the skeletal elements that can be repositioned.^{28,29} Most surgeons use a combination of analyses that incorporate Steiner's SNA, SNB, and ANB analysis for the

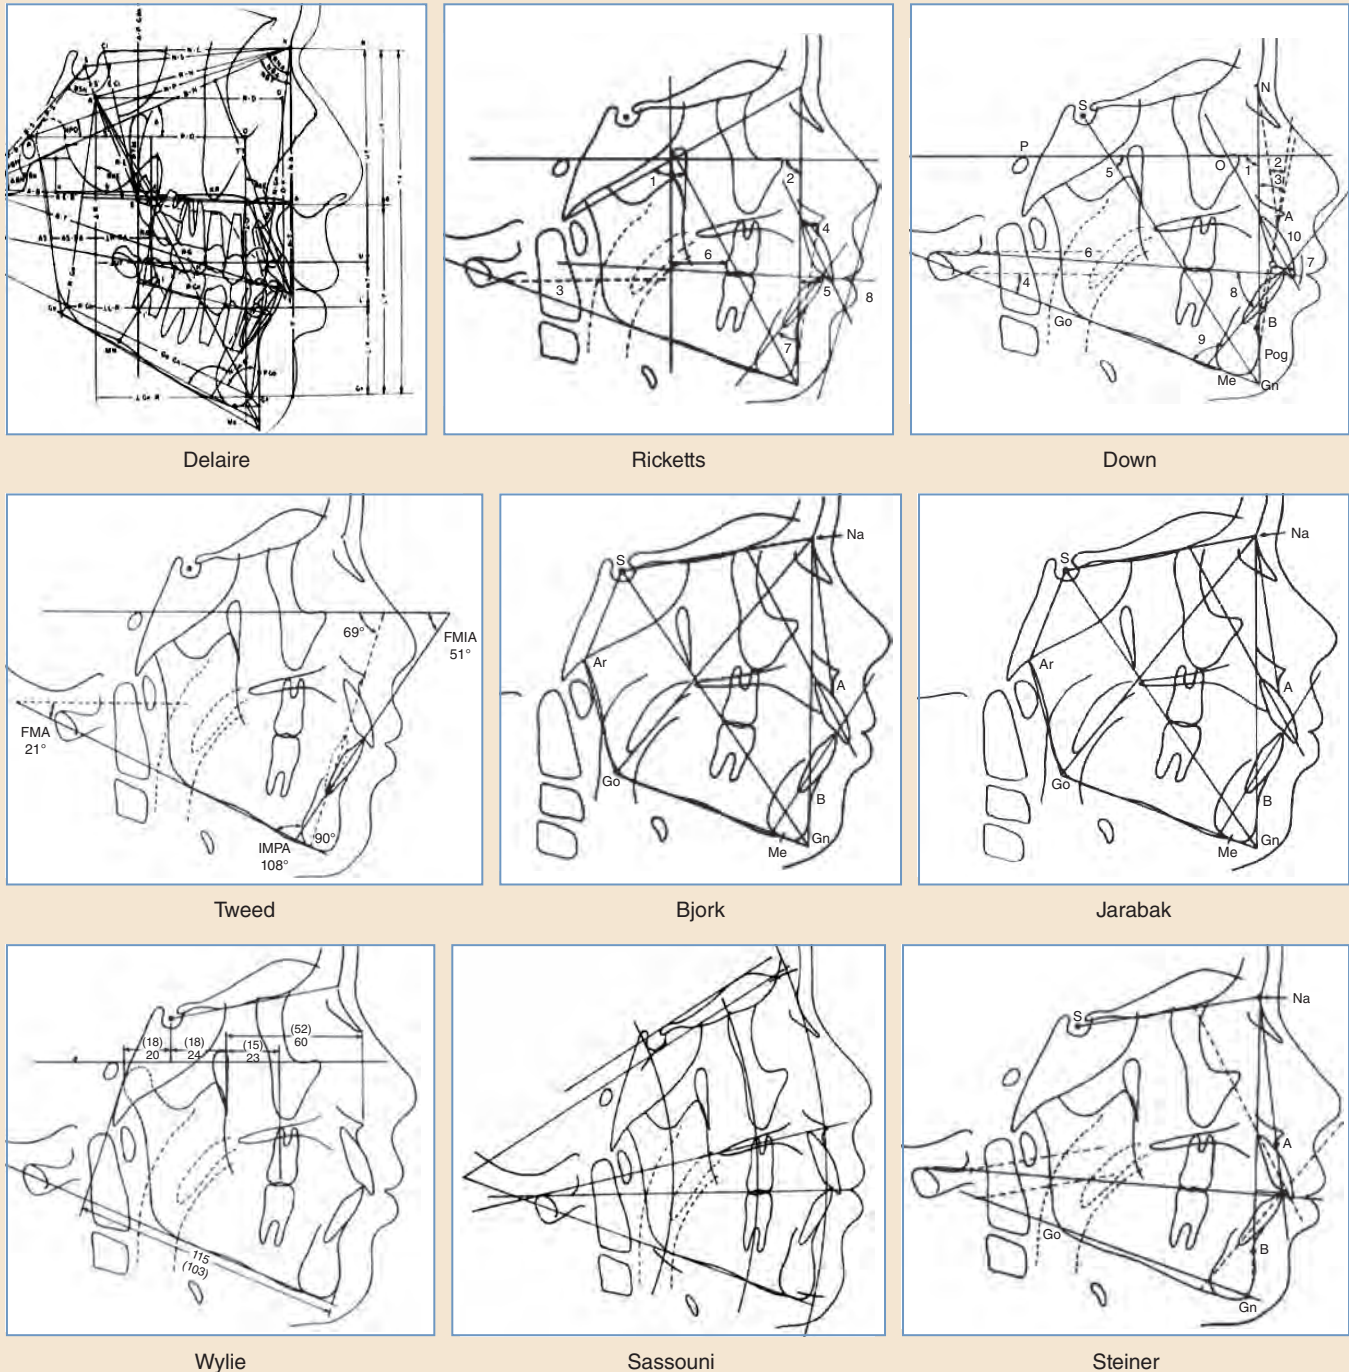

Fig. 27-10 Numerous cephalometric analyses exist to quantify the facial skeletal deformity. The choice of which analysis to use depends on the specific aspects of the deformity that interest the orthodontist and surgeon.

dynamic hard and soft tissue skeletal relationships. Furthermore, cephalometric soft tissue and skeletal analysis attempts to quantify the dentofacial skeletal deformity in angular-linear measurements, which fails to take into account the complexity of the relationship between multidimensional surface contours of the soft tissue and the underlying skeletal framework. The final decision must be based on three-dimensional assessment of the deformity and not on normalizing the facial skeleton and soft tissue envelope to two-dimensional static normative data.

The emergence of low-dose radiation CT scanners, such as cone-beam computed tomography (CBCT) scanning, has increasingly replaced the use of traditional lateral and frontal cephalometric radiographs for the skeletal assessment of patients for orthognathic surgery. With a single scan, the three-dimensional facial skeletal structure can be captured and from which the

Table 27-1 Typical Presentation of Dentofacial Skeletal Deformities

traditional cephalometric radiographs and panorex can be digitally extracted. Moreover the ability to capture the facial skeleton in 3D allows assessment of the asymmetries in all three planes. The CBCT eliminates the inherent limitations of assessing the complexity of a three-dimensional facial skeleton with traditional 2D orthogonal radiographs (the lateral and frontal cephalometric radiographs). However, despite the detailed information useful to the surgeon provided by the CBCT, the use of conventional 2D lateral cephalometric and panorex radiographs remains the primary mode of skeletal assessment for the vast majority of the orthodontic practices because of the expense of the CBCT unit and the trade-off of increased radiation in routine cases. In the vast majority of referrals to the surgeon, the orthodontist will review the traditional 2D lateral cephalometric analysis with the surgeon, and the surgeon will determine the need to capture the three-dimensional facial skeleton with CBCT. Although a discussion of the pros and cons of CBCT versus conventional cephalometric radiographs is beyond the scope of this chapter, these are mentioned because advances in technology will continue to have an impact on clinical practice.

Occlusal Evaluation

Surgical movements of the maxilla and mandible inherently alter the maxillary-mandibular dental occlusion; as such, careful analysis of the dental arches is necessary, working with the orthodontist. The dental arches are studied with either traditional plaster/stone dental casts that can be hand manipulated to assess how well the dental arches are coordinated, or increasingly today, optical scanning is used, which allows digital manipulation of the dental arches on a computer. Assessment of the dental arches includes an analysis of space and arch length, transverse width discrepancies, position of the individual tooth within its own arch, and the relationship of the maxillary and mandibular dentition (Fig. 27-13). The stability of surgical repositioning of the maxilla and mandible will ultimately depend on achieving a stable occlusal relationship, and the use of dental casts will allow visualization of the role of supportive orthodontic management to achieve the skeletal surgical goals.^{3,5} The diagnosis is then established from a working list of problems generated from clinical and photographic evaluations, cephalometric analysis, and dental study models.

Thus, to correct dentofacial skeletal deformities, the role of the orthodontist is equal in importance to that of the surgeon, inasmuch as treatment requires the coordinated efforts of both. There must be a close working relationship between the orthodontist and surgeon, because the goals of presurgical orthodontic treatment are the opposite of the routine orthodontic treatment used to camouflage skeletal discrepancies in patients who choose not to pursue surgery or in situations in which the orthodontist and patient decide that the skeletal discrepancy is not significant enough to warrant surgical correction. Proper occlusion can be achieved with orthodontic treatment alone in minor skeletal discrepancies, and at times even in more significant discrepancies; however, it is frequently at the expense of facial appearance.

These same patients who have undergone orthodontic treatment with no consideration given to combined surgical-orthodontic management may seek plastic surgery procedures later in life to address residual skeletal deformities.³⁰ After proper occlusion is achieved, skeletal correction is compromised and frequently requires the use of prosthetic implants and soft tissue procedures to camouflage the deformity, the results of which are less than ideal.

The answer to the question of when is the problem too severe for orthodontic treatment alone depends on the severity and the patient's age at presentation. With the same degree of severity, orthodontic treatment in children who are still growing is likely to have a favorable influence and may help to avoid the need for orthognathic surgery, with the exception of clefts and craniofacial abnormalities. In adults with the same degree of severity, surgery is the only option. However, when the malocclusion persists in the growing child despite the use of orthodontic

treatment to modify growth, surgical correction should be considered either during active growth or when the patient is skeletally mature.

A successful outcome is one in which both the occlusal goals and aesthetic goals are achieved. In the opinion of many orthodontists, the limitations of orthodontic treatment lie within the confines of a positive overjet of +8 mm, a negative overjet of -4 mm, and a transverse width discrepancy of 3 mm.³¹ The well-known discrepancy diagram of Proffit and colleagues^{32,33} illustrates the envelopes of achievable outcomes based on orthodontic treatment alone (inner envelope), orthodontic treatment in a growing child (middle envelope), and with orthognathic surgery (outer envelope) (Fig. 27-14). The envelopes are asymmetrical and different for the maxilla and mandible. The precise dimensions of the envelopes are less important than the philosophic concepts that must be applied to each case.

Fig. 27-13 Dental models are used to assess dental dysplasia. **A**, Arch form. **B**, Occlusion.

Fig. 27-14 The discrepancy diagram developed by Proffit's group for **A**, maxillary and **B**, mandibular dentition. The envelopes represent the amount of dental repositioning possible by orthodontic movement alone (yellow), orthodontic movement with growth modification (green), and with orthognathic surgery (blue). Note that the envelopes are not symmetrical and that, for example, orthodontic movement in the growing child is more effective with mandibular deficiency than with mandibular excess.

Growth and Development of the Maxillofacial Skeleton

A thorough knowledge of normal facial growth is important if abnormal patterns of growth are to be understood. Infants have a disproportionately large head and a small face, with eyes that appear large and widely set, a small nose, full cheeks, and a small lower jaw. It is this combination of features that makes infants so adorable. The same combination in skeletally mature adolescents would not elicit the same emotions. With the passage of time, the face emerges from beneath the cranium. The midface becomes more prominent, the eyes more deeply set beneath a brow, the nose more sharply defined, the lower jaw catches up, and the chin develops. Whether a person goes from being an adorable infant to an attractive or handsome adolescent depends on the proportions of the individual components. Thus a change in size and shape in all three dimensions occurs. The growth and development of the face from infancy to maturity occur at different rates, both spatially and temporally, where various elements of the face mature to differing extents and at different times (Fig. 27-15). Throughout this growth, the facial elements in their various stages of maturity remain interlocked anatomically and functionally.^{34,35}

By 3 or 4 years of age, the growth of the brain, and correspondingly the skull, slows considerably, and by approximately 6 years of age, the cranioorbital regions reach nearly 90% of the adult size.³⁶ In contrast to the deceleration in the cranial region, the facial bones begin to grow and develop throughout the remaining years of childhood and into adolescence. Whereas the midface (maxilla) reaches skeletal maturity in early adolescence, the lower facial skeleton (the mandible) continues to grow well into adolescence. There is a difference between the sexes; girls reach skeletal maturity in early adolescence (14 or 15 years of age) and boys in late adolescence and early adulthood (17 to 21 years of age). In addition, there are differences in growth in each of

Fig. 27-15 Skeletal maturity of the cranial vault, maxilla, and mandible from infancy to skeletal maturity (100% of adult size). The cranial vault reaches maturity long before the midface, followed by the mandible.

the facial dimensions. The width of the face reaches skeletal maturity long before the final maturity in the vertical length of the face.³⁴⁻³⁷

The basicranium itself has a significant influence on facial form, as the posterior boundary of the facial mass coincides with the boundary of the anterior and middle cranial fossa. Early on, with expansile growth of the anterior and middle cranial fossa with brain growth, the nasomaxillary complex and mandible are affected. This results in anteroinferior displacement within the nasomaxillary complex and vertical displacement of the mandible. By 5 or 6 years of age, growth in the frontal lobe and anterior cranial fossa nearly ceases; however, growth of the middle cranial fossa continues for several more years, which adds to the forward displacement of the nasomaxillary complex and vertical displacement of the mandible.³⁸⁻⁴⁰

Simultaneously, within the facial mass itself, bone deposition occurs at the various facial sutures and surfaces to allow volumetric enlargement while undergoing resorption along opposing surfaces. Sagittal lengthening of the maxillary arch occurs, with progressive bone deposition along the posterior surface of the maxillary tuberosity. Simultaneously, bone deposition along the lateral surface at the tuberosity increases the transverse width of the arch. With this posterior growth, the entire maxilla undergoes forward displacement in an anterior direction. Similarly, with the malar complex, growth (bone deposition) occurs along the posterior and lateral surfaces while simultaneously the anterior and medial surfaces undergo resorption. The malar complex maintains its continuity with the maxilla and also undergoes a forward displacement with posterior growth.³⁸⁻⁴⁰

The body of the mandible, of necessity, must undergo lengthening to match the maxillary arch. The anterior surface of the ramus undergoes remodeling by converting ramus to corpus. To maintain the width of the ramus, bone is added posteriorly. This backward sagittal growth then results in forward displacement of the mandible as a whole, such as with the maxilla. At the posterior region of the ramus, there are two distinct areas of growth: the posterior edge of the ramus itself and the condyle. Although the posterior edge is a sagittal growth direction, the growth of the condyle results in an angular vector that is posterior and superior. The condylar growth results in the anteroinferior displacement of the mandible. The ramus becomes progressively more upright by the anterior remodeling that occurs at its base to lengthen the mandibular body, and simultaneously comparatively more bone deposition occurs at the base of the posterior edge of the ramus. Essentially this results in rotation of the ramus, and the condylar growth vector is correspondingly more vertical, with a decrease in the gonial angle. This vertical lengthening then continues long after the horizontal ramal width ceases. This allows simultaneous accommodation of the vertical growth of the nasomaxillary complex without changing the occlusal relationship. Any difference in this interlocking growth pattern between the maxilla and mandible will lead to a skeletal sagittal discrepancy and/or a rotational imbalance (Fig. 27-16). There must also be a corresponding match that occurs in the transverse width between the jaws.³⁸⁻⁴⁰

Dental development plays an important role in maxillary-mandibular alveolar development. There are two aspects. One is dental eruption itself, and the other is the “drifting” of the tooth as a whole within the alveolar process. Movement of the tooth itself involves a process of similar remodeling of the tooth, its socket, and the periodontal membrane. While growth is present, the orthodontist can guide the individual teeth into position, taking advantage of the active phase of development with braces. In contrast, other orthodontic interventions, such as face masks and restraining chin cups, can alter the vector of the displacements of the maxilla and mandible, including the dental unit as a whole by affecting the sutures and sites of regional growth. These orthodontic maneuvers can have a significant and stable impact on future facial skeletal development only while growth is active and can be modulated (orthodontic growth modification).⁴¹⁻⁴³

Fig. 27-16 Growth and development of the facial skeleton. **A**, Counterclockwise development of the basicranium (*arrows*) displaces the mandible anteriorly. **B**, With growth of the interface, the mid-face is displaced in the anteroinferior vector (*arrow*). **C**, With growth at the posterior ramal border and condyle, the mandible is displaced in the anteroinferior vector (*arrow*). These displacements of the maxilla and mandible must match to maintain the normal maxillary-mandibular occlusal relation. Any discrepancy leads to dentofacial skeletal deformity.

Surgical intervention at an early age is often not questioned in children who have a severe deformity that is a result of either a congenital or acquired condition. However, children who present with a moderate deformity with a dental malocclusion are the ones who have problems in the timing and sequencing of treatment. A fundamentally correct treatment plan instituted at the wrong time in a child's development can yield a poor result. Thus the timing of the intervention becomes the more critical issue facing the orthodontist and surgeon.^{44,45}

If the skeletal malalignment is minimal to moderate, it is possible to achieve correction by influencing the pattern of jaw growth with interceptive facial orthopedic treatment. This interceptive treatment must be initiated during the periods of active growth in early to late childhood but before the adolescent growth spurt. By the time the child has reached sexual maturity, it is too late to attempt such treatment.

It makes sense in most cases of moderate deformity to wait until skeletal maturity when planning for orthognathic surgery to avoid reoperation because of recurrence of the deformity with continued disproportionate growth. There is a variation between the sexes with regard to the timing of skeletal maturity. Serial cephalometric radiographs will objectively indicate deceleration of growth, and a hand-wrist radiograph can be used to determine skeletal age.⁴⁶⁻⁴⁸ However, there are circumstances in which relying solely on ensuring the stability of the correction to determine the timing of surgery may be inappropriate. Adolescents who have a poor self-image and those who are socially introverted or victims of ridicule can greatly benefit from early intervention. Similarly, functional indications—speech, airway, and occlusion—may dictate earlier intervention. The decision regarding when to operate is complex and requires that patients and their parents be well informed, frequently guided by input from other members of the team.

OVERVIEW OF ORTHODONTIC-SURGICAL MANAGEMENT

Treatment planning begins with a review of the various orthodontic and surgical options available that will address the list of problems. The primary decision that must be made is whether the deformity is significant enough to require surgical repositioning, or orthodontic alignment of the dentition alone can be achieved without significantly compromising facial aesthetics. If surgical intervention is contemplated, the question then arises regarding whether to intervene before the completion of skeletal growth or wait for skeletal maturity to eliminate the variability of subsequent growth and the need for further surgical intervention. After the decision is made to combine dental and surgical correction, the overall treatment must be carefully planned. Thus formulating a treatment plan requires close cooperation between the surgeon, dentist, orthodontist, and at times the restorative prosthodontist. Unlike many surgical procedures, the outcome depends not only on the surgical procedure itself but also on a multitude of factors that begin long before the actual surgery and control of the variables long after the surgery.⁴⁹ The management (Fig. 27-17) can be divided into the following five phases: (1) the preorthodontic preparatory phase (dental care and oral hygiene), (2) presurgical orthodontic treatment phase, (3) surgical phase, (4) postsurgical orthodontic phase, and (5) prosthodontic and restorative treatment phase.

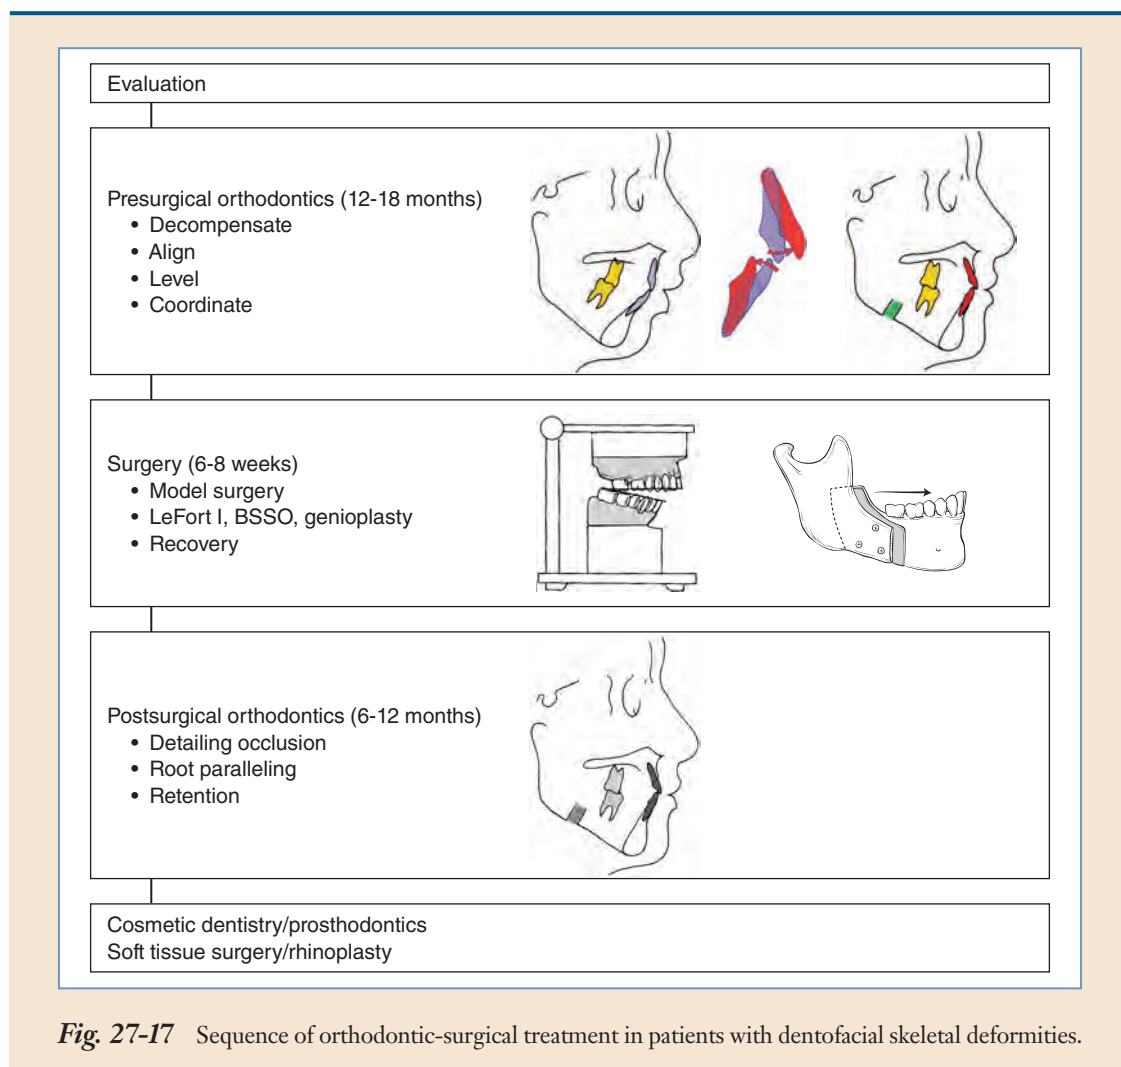

Fig. 27-17 Sequence of orthodontic-surgical treatment in patients with dentofacial skeletal deformities.

Dental Care and Oral Hygiene

Before the formal start of the presurgical orthodontic treatment phase, acute periodontal disease and caries must be managed as part of this initial phase.⁵⁰⁻⁵² Patients with periodontal disease and gingivitis have an increased risk of exacerbation with long-term application of orthodontic appliances, tooth movement, and during the postoperative period. Gingival inflammation must be reduced with cleaning and good oral hygiene. Poorly attached gingiva must be treated before any orthodontic tooth movement. Decisions must be made regarding whether carious dentition can be either temporarily or permanently restored, whether any endodontic treatment is required, or whether teeth should be extracted.

Presurgical Orthodontic Treatment

Once the state of oral hygiene is maximized, the presurgical orthodontic treatment phase can begin.⁵³⁻⁵⁷ With skeletal discrepancies, the teeth naturally compensate to establish as functional an occlusion as possible within the limitations of the deformity. The goal of the presurgical orthodontic preparation is to remove the dental compensations to reveal the true extent of the skeletal deformity. The teeth are orthodontically repositioned to their ideal position (axial inclination and alignment) within their respective maxillary and mandibular dental arches. Thus the occlusion is made worse until surgical correction occurs. Without appropriate dental decompensation, the surgeon is limited by the tooth position to fully correct the skeletal deformity. Thus the outcome depends on both the surgeon and orthodontist. The decompensation must be accomplished in all three dimensions: the sagittal plane (anteroposterior), the coronal plane (vertical), and the transverse plane (width) (Fig. 27-18).

In the transverse plane, the maxillary and mandibular dental arches need to be coordinated with the postsurgical occlusion (Fig. 27-19). Because of the relative transverse arch width discrepancy with class II and class III malocclusions, the dentoalveolar compensations must be removed. As with removal of the sagittal compensations, the arch width discrepancy is worsened. Depending on the discrepancy, the options are transpalatal orthodontic expansion with or without surgical assistance versus segmental maxillary osteotomies at the time of the formal orthognathic surgical procedure. Expansion may be accomplished orthodontically alone with a palatal expansion device if the midpalatal suture is open; otherwise, correction may require surgical assistance with an osteotomy. When interdental osteotomies are needed, orthodontic root divergence is necessary. Minor width discrepancies may be acceptable with some degree of orthodontic compensation and can frequently be corrected after surgery.

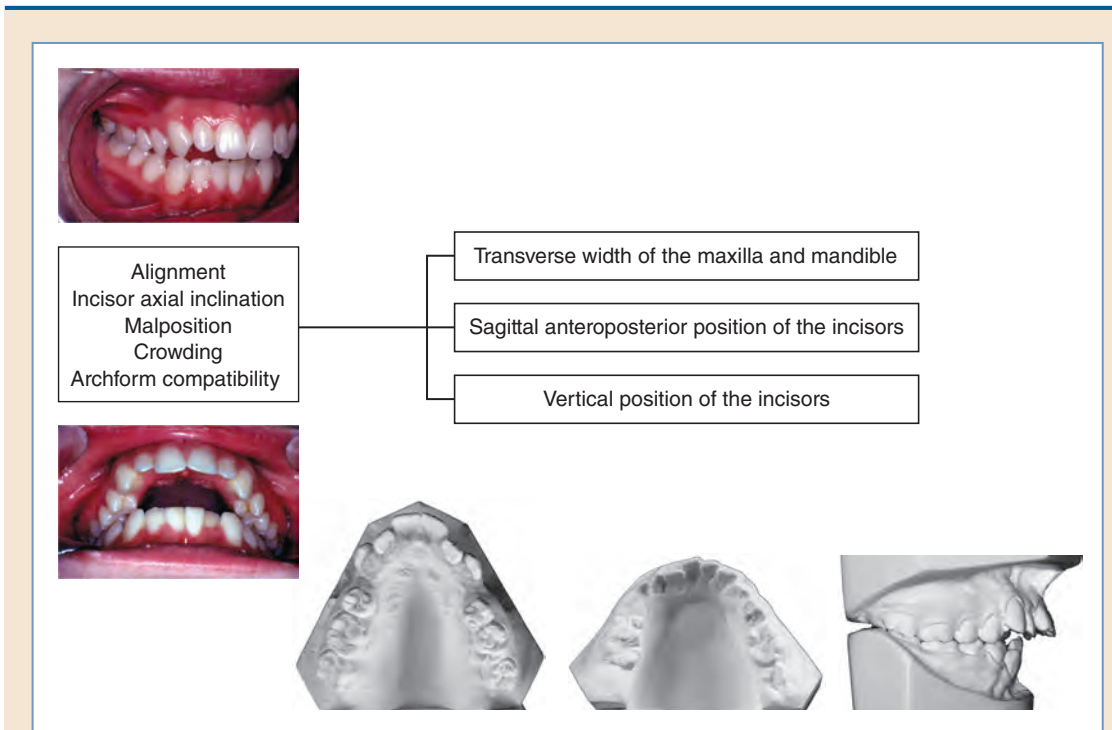

Fig. 27-18 Overview of presurgical orthodontic management.

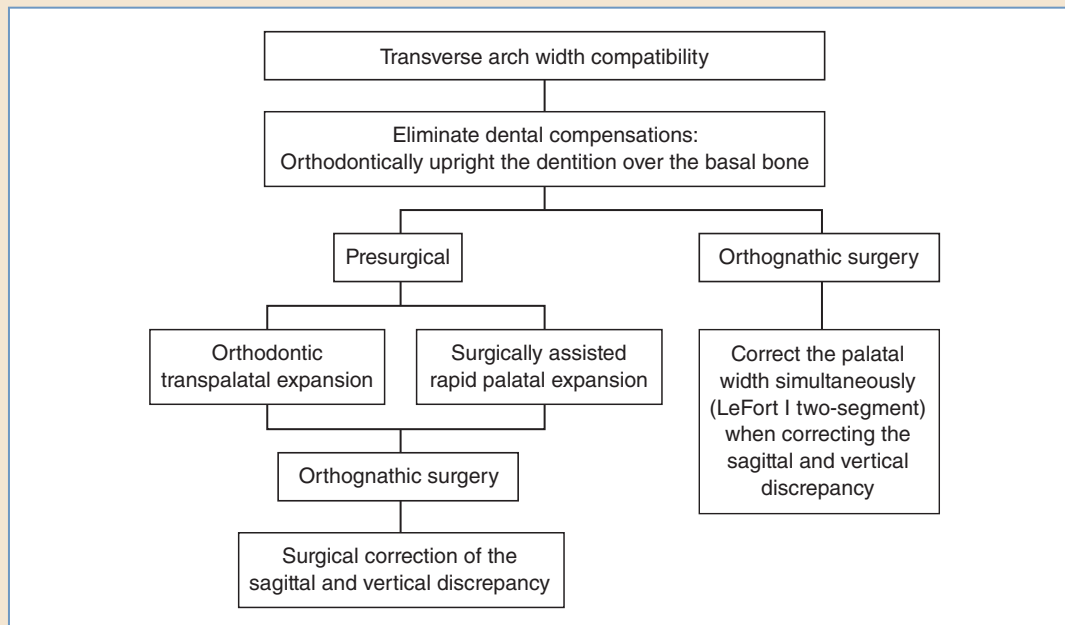

Fig. 27-19 Orthodontic management of the transverse component of dentofacial skeletal deformities.

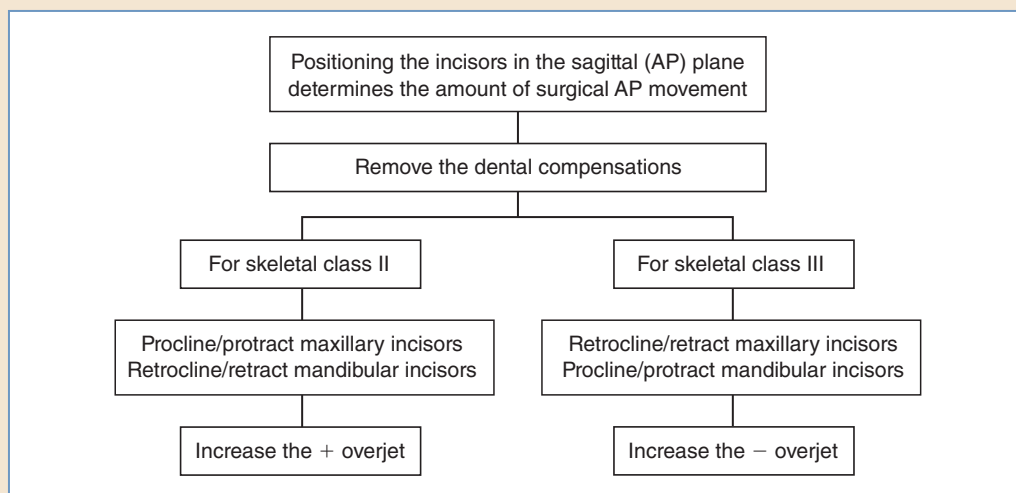

Fig. 27-20 Orthodontic management of the sagittal (anteroposterior [AP]) component of dentofacial skeletal deformities.

Fig. 27-21 Presurgical dental decompensation in the sagittal plane for class II and class III malocclusion. A goal of presurgical orthodontic management is to maximally decompensate the anterior dentition from pretreatment (*blue*) to presurgical (*red*) incisor position. As a consequence, the occlusion becomes worse. This allows the surgeon to reposition the skeleton so that when surgery is complete, the incisors are in an appropriate position with respect to their dental bases.

Anteroposterior decompensation involves correction of the maxillary and mandibular incisors (Figs. 27-20 and 27-21). In the typical class II malocclusion, the maxillary incisors are retroclined, and the mandibular incisors are proclined to allow a functional bite as a natural compensation to the skeletal deformity. Thus the decompensation involves orthodontically uprighting the proclined mandibular incisors. This may require removal of the mandibular first molars to relieve crowding if there is insufficient arch length to accommodate retraction and alignment of the incisors. In the maxilla, the opposite occurs. Decompensation of the maxillary incisors by proclination relieves any crowding typically without the need for extraction. Decompensation of class III malocclusion occurs in the reverse pattern.

In the vertical plane, dental decompensation of the anterior dentition depends on two factors: the amount of dental display of the maxillary incisors in relation to the upper lip and the lower anterior facial height (Fig. 27-22). When there is excessive dental display with gingival show in skeletal anterior open bite deformities, the extruded maxillary teeth that compensate for the open bite can be intruded orthodontically to a limited extent to level it in a single occlusal plane, with maxillary skeletal impaction surgery accomplishing most of the correction. Orthodontic correction alone will yield an unstable result. Frequently the posterior teeth may be in a significantly different occlusal plane from the anterior dentition. In such cases, if segmental maxillary repositioning is needed, the presurgical orthodontic treatment correspondingly involves segmental leveling in two different planes. In such cases, root diversion is needed to allow interdental osteotomies for a multisegmented LeFort I procedure.

In patients with a deep anterior incisor overbite, the decision of whether to level the occlusal plane depends on the lower facial height. When the lower facial height is normal, the deep bite is corrected by presurgically intruding the incisors. In contrast, when the lower facial height is

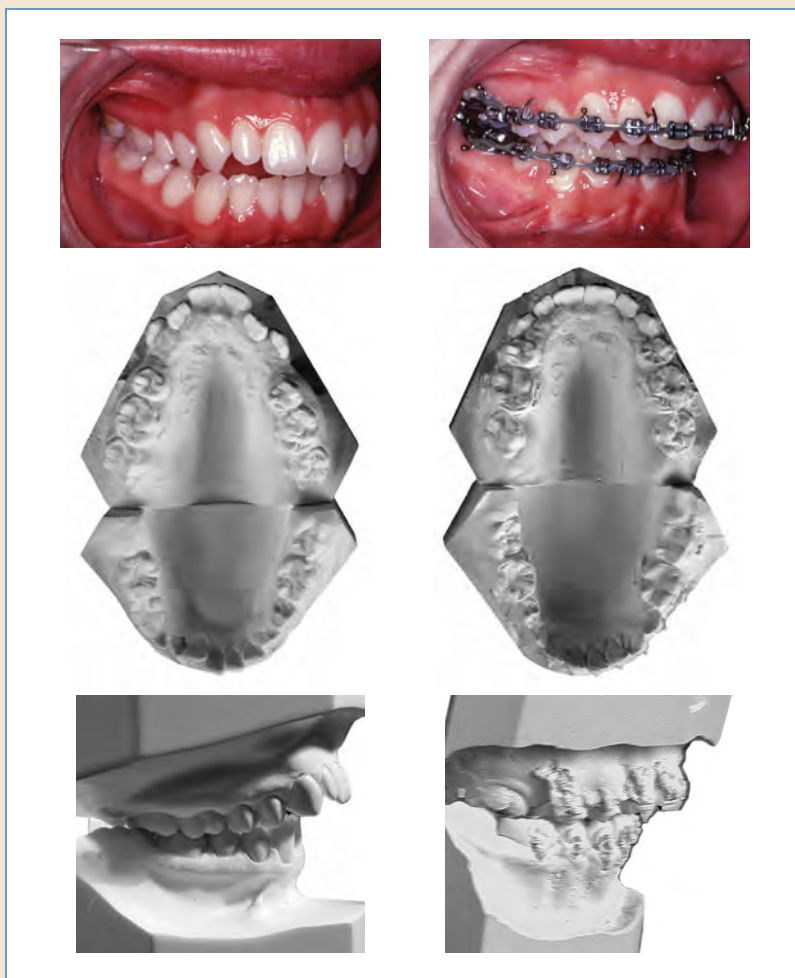

Fig. 27-23 Presurgical orthodontic management. The dentition has been aligned within the dental arches and decompensated to allow skeletal correction.
